Acknowledgments

In performing the modification of the numerical code, and conducting the experimentation, I have had a great deal of assistance from others.

I am deeply indebted to my thesis advisor, Maj James K. Hodge, and I would like to thank him for his knowledge, guidance, and trans-Atlantic assistance throughout the scope of this entire project.

I would like to thank my VKI project advisor, Prof John F. Wendt, for his guidance and advice on my project and experimental research techniques in general. I wish to thank Prof Tony Arts for giving his time to answer my many questions concerning thin film gages and halting his testing schedule so that I could use his equipment for my tests. I wish to express my sincere appreciation to Mr. Roger Conniasselle, the chief technical engineer of the VKI High Speed Department for his assistance and expertise, and also "merci beaucoup" to Mr. Oscar Opalvens who performed a seemingly endless amount of model changes without complaint. I also thank Eric Abriat for lending me his plotting program. I also wish to express my appreciation to Mr. J.C. Lobet for his assistance and his team for developing the many photographs that I required.

Last, but certainly not least, I wish to thank my husband, Bob, for his support and guidance even though we were separated by the Atlantic Ocean.

Alice J. Chen

List of Symbols

a	Speed of sound
A	Rake orientation angle
A	Van Driest damping parameter
⁺ A	Nondimensional Van Driest damping parameter
AOS	Chapman damping parameter
⁺ AOS	Nondimensional Chapman parameter
A*/ β	Calibration constant for the electrical analog
C	Electrical capacitance
C'	Distributed electrical capacitance per unit length
c_f	Skin friction coefficient
cp	Specific heat capacity at constant pressure
d	Derivative symbol
d	Diameter of fin leading edge
EPS	Maximum error allowed for computer code
H	Total enthalpy
h	Static enthalpy
h	Height of fin
h	Number of stages of arithmetically increasing components in the analog circuit
HC	Heat transfer coefficient
HREF	Reference heat transfer coefficient
H.O.T.	Higher order terms
I	Number of spatial node points in X or ξ direction
i	Node point in X or ξ direction

i	Electrical current
J	Number of spatial node points in Y or η direction
j	Node point in Y or η direction
k	Conductivity
k_T	Turbulent conductivity
K	von Karman's constant
L	Flat plate length
l	Separation distance ahead of the fin leading edge
l	Turbulent length scale, mixing length
l_o	Outer region mixing length
L_m	Mixing length parameter
L_m^C	Chapman's mixing length parameter
L_m^{VD}	Van Driest's mixing length parameter
M	Mach number
M_∞	Freestream Mach number
n	Number of stages in an identical component analog circuit
P	Static pressure
P_o	Stagnation pressure
Pr	Prandtl number
Pr_T	Turbulent Prandtl number
Q	Cumulative heating
q	Heat rate
q_w	Heat rate at the wall

R	Gas constant for air
R	Electrical resistance
RREF	Thin film resistance at temperature TREF
r	Recovery factor
r	Radial distance in the H-3 tunnel
r'	Distributed electrical resistance per unit length
Re	Reynolds Number per unit length
Rex	Local Reynolds Number, based on x distance downstream of the leading edge of the plate
s	Laplace variable
St	Stanton Number
T	Static temperature
Ta	Ambient temperature
T _{AW}	Adiabatic wall temperature
TF	Reference temperature for theoretical Stanton number calculation
T _∞	Freestream temperature
To	Stagnation temperature
TREF	Reference temperature, usually ambient
t	Time
U	Dorodnitsyn's transformation of streamwise flow velocity
u	Streamwise flow velocity
⁺ U	Nondimensional turbulent velocity scale
U _τ	Friction velocity

V	Dorodnitsyn's transformation of normal flow velocity
V	Electrical voltage
VOUT	Output voltage from analog circuit
VREF	Initial thin film voltage, taken at Ta
v	Normal flow velocity
ΔV	Film output voltage
X	Dorodnitsyn's transformation of streamwise spatial coordinate
x	Streamwise spatial coordinate
x	Streamwise direction in wind tunnel
x _{T,I}	Initial location of transition zone
x _{T,F}	Final location of transition zone
Y	Dorodnitsyn's transformation of normal spatial coordinate
Y	Normal spatial coordinate
⁺ Y	Nondimensional turbulent scale
α	Flat plate incidence angle, pitch up is positive
α	Thermal diffusivity
α_R	Film temperature coefficient of resistance
α^*	Clauser model factor to account for low Reynolds Number
β	Chapman's length scale
r	Transition parameter
γ	Specific heat ratio

Δ	Delta difference of some quantity
δ	Boundary layer thickness
δ^*	Kinematic displacement thickness
η	Transformed Y in the computational plane
θ	Normalized streamwise coordinate in transition zone
θ	Shock angle
θ_s	Numerical stability constant
μ	Dynamic viscosity
μ_T	Turbulent viscosity
ξ	Transformed X in the computational plane
ρ	Density
σ	Intermittency parameter
ξ	Extent of transition
θ	Delta wing incidence angle
∂	Partial derivative symbol
Ω	Delta wing sweep angle

Superscripts

n	Time level
s	Iteration level
#	Dimensional quantity
*	Laplace transformed variable
'	Mass averaged variable-fluctuation
~	Mass averaged variable-mean
-	Time averaged variable-fluctuation
-	Time averaged variable-mean

Subscripts

e	Edge condition
i,j	Spatial node point
∞	Freestream condition
o	Stagnation property

Abstract

This study combines the techniques of computational fluid dynamics and experimentation.

An unsteady laminar boundary layer code was shown to be more efficient when modified to solve the momentum and energy equations using Thomas' algorithm instead of optimized successive over-relaxation (SOR). A steady eddy viscosity turbulence model was then added to the code: two models for the inner region, Van Driest and Chapman, and two models for the outer region, a mixing length and Clauser were used. The computer code was verified against theoretical and experimental data from the literature. The code shows excellent results for laminar flow and each of the models showed very good agreement with turbulent experimental data.

The experimental study was conducted in a Mach 6 blowdown wind tunnel. Oil flow, sublimation, liquid crystals, and thin film gages were used to examine the flow structure and heat transfer on a flat plate. The heat transfer rates from these gages were lower than from the liquid crystals. The viscid-inviscid interaction flow region of flow past a blunt fin mounted on the flat plate was examined using the same flow visualization methods and possible flow interaction models are presented. Striation heating appeared when the fin incidence was 40° and the sweep was 60 or 75° .

The numerical and experimental techniques of this study were then merged. The heat transfer results from the flat plate experiment were compared with results from the computer code and were found to be in good agreement.

I. Introduction

This research effort, as well as this report based on it, consists of three main parts; a computational part, an experimental part, and a comparison between experimental data obtained and results from the computer program. The computational part was completed at the Air Force Institute of Technology (AFIT), Wright-Patterson Air Force Base, Ohio, while the experimental part was completed at the von Karman Institute for Fluid Dynamics (VKI), Rhode-Saint-Genese, Belgium. The experimental research was sponsored by HQ USAF, AFIT, VKI, and the Flight Dynamics Laboratory at Wright-Patterson Air Force Base, Ohio.

The computational effort consisted of modifying an unsteady laminar boundary layer code to a turbulent boundary layer code. The computational effort originally consisted of adding an unsteady turbulence model (38) to the unsteady laminar boundary layer code. However, due to time limitations, only a steady eddy viscosity turbulence model was added. Two models for the turbulent length scale were included, the Van Driest model and the Chapman model. The theory and results of these two models were compared with one another. Two models for the turbulent viscosity in the outer region are also examined; the mixing length model and Clauser's formulation of the mixing length model. A transition (laminar to turbulent) model was also included in the modification of the boundary layer code.

The experimental effort consisted of the study of a sharp nosed flat plate at zero degrees angle of attack. Heat transfer measurements were taken to determine the location of transition and turbulence. A swept blunt fin at incidence was placed on the flat plate and studied using flow visualization. This configuration was chosen due to its similarity to the configuration of the NASA Space Shuttle side fuselage and blunt fin. The Shuttle experiences high heat transfer rates on its side fuselage during re-entry, so the experimental effort originally was envisioned to concentrate on examining heat transfer rates on the flat plate on the expansion side of the blunt fin in laminar flow. Flight data has shown the existence of laminar flow on the Shuttle during many flight regimes including re-entry. Due to time limitations, only flow visualization tests were completed for this configuration. Effects of fin incidence and sweep angle are examined and possible models for the flow interaction region are suggested. Previous studies at VKI have examined this configuration on the expansion side (14), the compression side (15), (53), and the impingement portion (1) of the fin during turbulent flow.

The third part of this study ties the first and the second portions of this study together. Although computational fluid dynamics has recently become more important in determining flow properties about flight

vehicles, it can never exist without experimental data. As each computer code becomes developed, it must be verified for accuracy using experimental data. The third portion of this thesis blends a portion of the separate computational and experimental efforts by verifying the computer code using some of the experimental results from this study.

II. Computational Effort

2.1 Introduction

The computational aspect of this research dealt with the modification of an unsteady compressible laminar boundary layer code to a compressible turbulent boundary layer code. Time limitations caused only a steady turbulence model to be added to the code. A transition to turbulence model was also included. The applicable portions of the laminar boundary layer code are described in a later section.

Three major modifications were made to the original program. The momentum and energy equations were originally solved by the program using optimized successive over-relaxation. This was changed to take advantage of the diagonal dominance inherent in the finite differencing. Thomas' algorithm, which is a tridiagonal solver, was modified to a quad-diagonal solver. The momentum and energy equations were solved using this quad-diagonal solver.

The second major modification was the inclusion of the Cebeci-Smith turbulence model. Prandtl's mixing length theorem was used which included the Van Driest model for the turbulent length scale in the inner region. The Chapman model was also used for the inner region length scale and the differences between the two models are examined. For the outer region, two different models were examined and compared: a mixing length model and the Clauser model.

The third major modification was the addition of a transition to turbulence model. Given the location of the beginning of transition and the end of transition (fully turbulent), the model uses an exponential distribution to match the turbulent viscosity between the two regions.

2.2 Governing Equations

The Navier-Stokes equations for a viscous compressible flow are simplified using normal boundary layer assumptions. That is, gradients perpendicular to the surface are much larger than gradients parallel to the surface. The terms of the order of magnitude of the inverse square of the characteristic Reynolds number are neglected. The resulting boundary layer equations in conservative form are:

continuity

$$\frac{\partial \rho\#}{\partial t\#} + \frac{\partial \rho\#u\#}{\partial x\#} + \frac{\partial \rho\#v\#}{\partial Y\#} = 0 \quad (2.1)$$

x-momentum

$$\frac{\partial \rho\#u\#}{\partial t\#} + \frac{\partial \rho\#u\#u\#}{\partial x\#} + \frac{\partial \rho\#u\#v\#}{\partial Y\#} = - \frac{\partial P\#}{\partial x\#} + \frac{\partial}{\partial Y\#} \left[\mu\# \frac{\partial u\#}{\partial Y\#} \right] \quad (2.2)$$

Y-momentum

$$\frac{\partial P\#}{\partial Y\#} = 0 \quad (2.3)$$

energy

$$\frac{\partial \rho^{\#} H^{\#}}{\partial t^{\#}} + \frac{\partial \rho^{\#} u^{\#} H^{\#}}{\partial x^{\#}} + \frac{\partial \rho^{\#} v^{\#} H^{\#}}{\partial y^{\#}} = \frac{\partial P^{\#}}{\partial t^{\#}} + \frac{\partial}{\partial y^{\#}} \left[k^{\#} \frac{\partial T^{\#}}{\partial y^{\#}} \right] + \frac{\partial}{\partial y^{\#}} \left[\mu^{\#} u^{\#} \frac{\partial u^{\#}}{\partial y^{\#}} \right] \quad (2.4)$$

These equations have boundary conditions at the edge of the boundary layer and at the wall.

2.2.1 Time and Mass-Weighted Averaging

In order to obtain the governing equations for turbulent flows, it is convenient to replace the instantaneous quantities in the equations by their mean and fluctuating quantities. A combination of conventional time averaging and mass-weighted averaging will be used as outlined in Cebeci and Smith (7:49-55).

The time averaged variables are defined as follows:

$$\begin{aligned} \bar{\rho} &= \bar{\rho} + \rho'' \\ \bar{P} &= \bar{P} + P'' \end{aligned} \quad (2.5)$$

where $\bar{\rho}$ and \bar{P} are the time averages of the bulk density and pressure, respectively, and ρ'' and P'' are the superimposed density and pressure fluctuations, respectively. The time average or "mean" of any quantity, $q(t)$, is defined by

$$\bar{q}(t) = \lim_{\Delta t \rightarrow \infty} \frac{1}{\Delta t} \int_{t_0}^{t_0 + \Delta t} q(t) dt \quad (2.6)$$

where $\bar{\omega}$, as defined by Cebeci and Smith (7:49), is taken to mean

"a time that is long compared to the reciprocal of the predominant frequencies in the spectrum of q ; in wind tunnel experiments, averaging times of a few seconds to a minute are usual."

For a fluctuating quantity $q''(t)$, the mean is zero by definition, i.e.,

$$\overline{q''(t)} = 0 \quad (2.7)$$

therefore,

$$\overline{\phi''} = 0 \quad (2.8)$$

$$\overline{p''} = 0$$

The mass-weighted variables are defined as follows:

$$\begin{aligned} \tilde{u} &= \bar{u} + u' \\ \tilde{v} &= \bar{v} + v' \\ \tilde{H} &= \bar{H} + H' \\ \tilde{T} &= \bar{T} + T' \end{aligned} \quad (2.9)$$

A mass-weighted mean quantity is defined as:

$$\tilde{q} = \frac{\overline{\phi q}}{\bar{\phi}} \quad (2.10)$$

where the bar denotes conventional time averaging and the tilde denotes mass-weighted averaging. A consequence of combining the time and mass-weighted averaging is that

$$\overline{\rho u'} = 0$$

$$\overline{\rho v'} = 0$$

$$\overline{\rho H'} = 0$$

$$\overline{\rho T'} = 0$$

(2.11)

Applying the mass-weighted averaging on the boundary layer equations and then taking the mean, results in a complicated set of equations. An order of magnitude analysis can be used to determine which terms are small enough that they may be neglected. An assumption used in the averaging technique is that fluctuations in the transport properties μ and k are ignored. Since the temperature is allowed to fluctuate, this is an important assumption since μ and k are both functions of the temperature. Details of the averaging are described in Appendix A. The order of magnitude analysis used in this study parallels the analysis in Cebeci and Smith (7:71-78). The resulting set of boundary layer equations for turbulent flow are:

continuity

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u}{\partial x} + \frac{\partial \rho v}{\partial y} = 0 \quad (2.12)$$

x-momentum

$$\begin{aligned} \frac{\partial \rho u}{\partial t} + \frac{\partial \rho u u}{\partial x} + \frac{\partial \rho u v}{\partial y} + \frac{\partial \rho u u' v'}{\partial y} = - \frac{\partial P}{\partial x} \\ + \frac{\partial}{\partial y} \left[\mu \frac{\partial u}{\partial y} \right] \end{aligned} \quad (2.13)$$

y-momentum

$$\frac{\partial \bar{P}}{\partial Y} = 0 \quad (2.14)$$

energy

$$\begin{aligned} \frac{\partial \bar{\rho} \bar{H}}{\partial t} + \frac{\partial \bar{\rho} \bar{u} \bar{H}}{\partial x} + \frac{\partial \bar{\rho} \bar{v} \bar{H}}{\partial Y} + \frac{\partial \bar{\rho} \bar{v}' \bar{H}'}{\partial Y} = \frac{\partial \bar{P}}{\partial t} \\ + \frac{\partial}{\partial Y} \left[\frac{k}{c_p} \frac{\partial \bar{H}}{\partial Y} \right] + \frac{\partial}{\partial Y} \left[\left[\mu - \frac{k}{c_p} \right] \frac{\partial}{\partial Y} \left(\frac{1}{2} \bar{u} \bar{u} \right) \right] \end{aligned} \quad (2.15)$$

These eqns (2.12), (2.13), (2.14), and (2.15) are similar to the corresponding original eqns, (2.1), (2.2), (2.3) and (2.4), except for an additional term in the x-momentum equation and one in the energy equation. The additional term in the momentum equation, is called the Reynold's stress. These two additional terms from the momentum and energy equations are listed in eqns (2.16) and (2.17) and must be defined before the governing equations can be solved.

$$\text{Reynold's stress term} \quad -\bar{\rho u' v'} \quad (2.16)$$

$$\text{energy transport term} \quad \bar{\rho v' H'} \quad (2.17)$$

Note the last two terms in the energy eqn (2.4) are the same as the last two terms in eqn (2.15), just rewritten in another form.

2.2.2 Closure Equations

Before the continuity, momentum, and energy equations, (2.12), (2.13), (2.14) and (2.15), can be solved, two more equations are needed for complete closure of the set of equations. Boussinesq (3:221) suggested that the apparent turbulent shear stresses might be related to the rate of mean strain through an apparent scalar turbulent or "eddy" viscosity. For the Reynold's stress term, eqn (2.16), the Boussinesq assumption gives

$$\overline{-\rho u'v'} = \mu_T \# \frac{\partial \bar{u}}{\partial Y} \quad (2.18)$$

where $\mu_T \#$ is a turbulent viscosity which will be defined later. The second closure equation (3:225; 7:239) uses a form of the Reynold's analogy which is based on the similarity between the transport of heat and momentum. Combining the Boussinesq assumption and Reynolds analogy:

$$\overline{\rho c_p v' T'} = -k_T \# \frac{\partial \bar{T}}{\partial Y} = -\mu_T \# \frac{c_p \#}{Pr} \frac{\partial \bar{T}}{\partial Y} \quad (2.19)$$

where $k_T \#$ is the turbulent conductivity. Substituting in the closure eqns (2.18) and (2.19), the eqns (2.12), (2.13), (2.14), and (2.15) become:

continuity

$$\frac{\partial \bar{\rho}}{\partial t} + \frac{\partial \bar{\rho} u}{\partial x} + \frac{\partial \bar{\rho} v}{\partial Y} = 0 \quad (2.20)$$

x-momentum

$$\frac{\partial \bar{\rho} \bar{u}}{\partial t} + \frac{\partial \bar{\rho} \bar{u} \bar{u}}{\partial x} + \frac{\partial \bar{\rho} \bar{u} \bar{v}}{\partial y} = - \frac{\partial \bar{P}}{\partial x} + \frac{\partial}{\partial y} \left[\left[\mu + \mu_T \right] \frac{\partial \bar{u}}{\partial y} \right] \quad (2.21)$$

y-momentum

$$\frac{\partial \bar{P}}{\partial y} = 0 \quad (2.22)$$

energy

$$\begin{aligned} \frac{\partial \bar{\rho} \bar{H}}{\partial t} + \frac{\partial \bar{\rho} \bar{u} \bar{H}}{\partial x} + \frac{\partial \bar{\rho} \bar{v} \bar{H}}{\partial y} &= \frac{\partial \bar{P}}{\partial t} + \frac{\partial}{\partial y} \left[\left[\frac{\mu}{Pr} + \mu_T \right] \frac{\partial \bar{H}}{\partial y} \right] \\ &+ \frac{\partial}{\partial y} \left[\mu (1 - 1/Pr) \frac{\partial (1/2 \bar{u} \bar{u})}{\partial y} \right] \\ &+ \frac{\partial}{\partial y} \left[\mu_T \left[1 - 1/Pr \right] \frac{\partial (1/2 \bar{u} \bar{u})}{\partial y} \right] \end{aligned} \quad (2.23)$$

Note that in many references, since the last term in equation (2.23) is very small, it is usually omitted.

The substitution of the Reynolds stress term into the x-momentum equation is mathematically trivial. However, for completeness, the mathematical steps of substituting the closure equations into the energy equation are displayed in detail in Appendix B.

2.2.3 Nondimensionalization

The turbulent boundary layer equations (2.20), (2.21), (2.22), and (2.23), are nondimensionalized using these factors.

$$\begin{aligned} x &= \frac{x\#}{L\#} & Y &= \frac{Y\#}{L\#} & t &= \frac{t\#U_{\infty}\#}{L\#} & u &= \frac{u\#}{U_{\infty}\#} & v &= \frac{v\#}{U_{\infty}\#} \\ \mu &= \frac{\mu\#}{\mu_{\infty}\#} & \phi &= \frac{\phi\#}{\phi_{\infty}\#} & H &= \frac{H\#}{U_{\infty}\#^2} & P &= \frac{P\#}{\phi_{\infty}\#U_{\infty}\#^2} \\ Pr &= \frac{c_p\#\mu\#}{k\#} & Re &= \frac{u\#L\#\phi\#}{\mu\#} \end{aligned} \quad (2.24)$$

The resulting turbulent boundary layer equations are:
continuity

$$\frac{\partial \phi}{\partial t} + \frac{\partial \phi u}{\partial x} + \frac{\partial \phi v}{\partial Y} = 0 \quad (2.25)$$

x-momentum

$$\frac{\partial \phi u}{\partial t} + \frac{\partial \phi u u}{\partial x} + \frac{\partial \phi u v}{\partial Y} = - \frac{\partial P}{\partial x} + \frac{\partial}{\partial Y} \left[\left[\mu + \mu_T \right] \frac{1}{Re} \frac{\partial u}{\partial Y} \right] \quad (2.26)$$

Y-momentum

$$\frac{\partial P}{\partial Y} = 0 \quad (2.27)$$

energy

$$\begin{aligned} \frac{\partial \phi H}{\partial t} + \frac{\partial \phi u H}{\partial x} + \frac{\partial \phi v H}{\partial Y} &= \frac{\partial P}{\partial t} + \frac{\partial}{\partial Y} \left[\frac{1}{Re} \left[\frac{\mu}{Pr} + \mu_T / Pr_T \right] \frac{\partial H}{\partial Y} \right] \\ &+ \frac{\partial}{\partial Y} \left[\frac{1}{Re} \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \frac{\partial}{\partial Y} \left(\frac{1}{2} \overline{uu} \right) \right] \end{aligned} \quad (2.28)$$

2.2.4 Dorodnitsyn Transformation

The Dorodnitsyn transformation (27:2-4) is used to scale these unsteady compressible boundary layer equations into a form similar to the incompressible boundary layer equations. This transformation is

$$\begin{aligned} X &= x & Y &= \int_0^Y \phi \, dy & t &= t & H &= H \\ U &= u & V &= \phi v + \frac{\partial Y}{\partial t} + \frac{u \partial Y}{\partial x} \end{aligned} \quad (2.29)$$

The nondimensional governing equations for turbulent boundary layer flow become

continuity

$$\frac{\partial \bar{U}}{\partial X} + \frac{\partial \bar{V}}{\partial Y} = 0 \quad (2.30)$$

x-momentum

$$\frac{\partial \bar{U}}{\partial t} + \bar{U} \frac{\partial \bar{U}}{\partial X} + \bar{V} \frac{\partial \bar{U}}{\partial Y} = - \frac{1}{\phi} \frac{\partial \bar{P}}{\partial X} + \frac{\partial}{\partial Y} \left[\left[\mu + \mu_T \right] \frac{\phi}{Re} \frac{\partial \bar{U}}{\partial Y} \right] \quad (2.31)$$

Y-momentum

$$\frac{\partial \bar{P}}{\partial Y} = 0 \quad (2.32)$$

energy

$$\begin{aligned} \frac{\partial \bar{H}}{\partial \bar{t}} + \frac{\bar{U} \partial \bar{H}}{\partial \bar{X}} + \frac{\bar{V} \partial \bar{H}}{\partial \bar{Y}} = \frac{1}{\bar{\rho}} \frac{\partial \bar{P}}{\partial \bar{t}} + \frac{\partial}{\partial \bar{Y}} \left[\left[\frac{\mu}{Pr} + \frac{\mu_T}{Pr_T} \right] \frac{\bar{\rho}}{Re} \frac{\partial \bar{H}}{\partial \bar{Y}} \right] \\ + \frac{\partial}{\partial \bar{Y}} \left[\frac{\bar{\rho}}{Re} \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \frac{\partial \bar{U}^2 / 2}{\partial \bar{Y}} \right] \quad (2.33) \end{aligned}$$

Now that the governing equations have been derived, the set of equations can be solved once the turbulent viscosity is known. Several models for the turbulent viscosity will be presented in section 2.4.2.

2.3 Description of Original Program

The original computer program solves the unsteady compressible boundary layer equations for laminar flow. The boundary layer equations are first nondimensionalized and then transformed using the Dorodnitsyn transformation. Then these equations are transformed to the computational plane and finite differenced. The momentum and energy equations are solved using optimized successive over-relaxation, while the method of solving the continuity equation has been modified by Coffey (11:34) and solves for the V velocity using trapezoidal integration.

The wall, edge, and initial conditions for the current work are all specified exactly as in the original program (34:34-36). However, the plate was assumed to be stationary

throughout all the investigations, ie., not pitching. Since all the cases performed for this effort were for a flat plate, the edge conditions were the same as the infinity conditions.

2.3.1 Grid

In the program, the flat plate length is 1.25 feet in the x direction and approximately two times the fully turbulent boundary layer thickness in the Y direction. The program originally had only 61 points in the streamwise direction and 30 points in the normal direction. Although the number of grid points were significantly fewer than other schemes, it produced similar results when compared to other computer codes and theory, but at a faster rate and less cost due to its sparse grid. However, more points in the normal direction were added when the turbulence model was introduced to the program. The program currently has a 61 by 59 point grid.

One of the unique features of the original code is a generalized grid. This adds great capability to the code by enabling it to handle several configurations. For the present analysis, the physical grid varied exponentially in the x direction. The Y step size varied according to an exponential and power law velocity profile (21). In this study, the grid had a $1/2$ power law which is optimum for laminar flow. For fully turbulent flow, a $1/7$ power law should be used for the grid. In cases of transition to

turbulence, an optimized grid could be used. This optimized grid could be developed using a grid generation program (22) and then optimized using the adaptive-grid method to minimize truncation error as explained by Coffey (11).

Since the flow is compressible, density variations will essentially cause the physical grid to change. The Dorodnitsyn transformation eliminates the density fluctuations and allows the program to utilize a fixed grid. The Dorodnitsyn fixed grid is shown in Figures 2.1 and 2.3. The physical grid at steady state is shown in Figures 2.2 and 2.4. Both the full grid and an expanded view are shown. Note that the grid is smooth in the computational (Dorodnitsyn grid) plane, but is not in the physical plane at the transition location of $x/L = 0.1$.

2.3.2 Computational Grid

A general transformation can be made to a rectangular computational grid. This grid is in the $\xi - \eta$ plane where ξ is in the streamwise direction and η is in the normal direction. The metrics ξ_X, ξ_Y, η_X , and η_Y that appear in the differential equations are solved using

$$\begin{aligned}\xi_X &= Y_\eta/J \\ \xi_Y &= -X_\eta/J \\ \eta_X &= -Y_\xi/J \\ \eta_Y &= X_\xi/J\end{aligned}\tag{2.34}$$

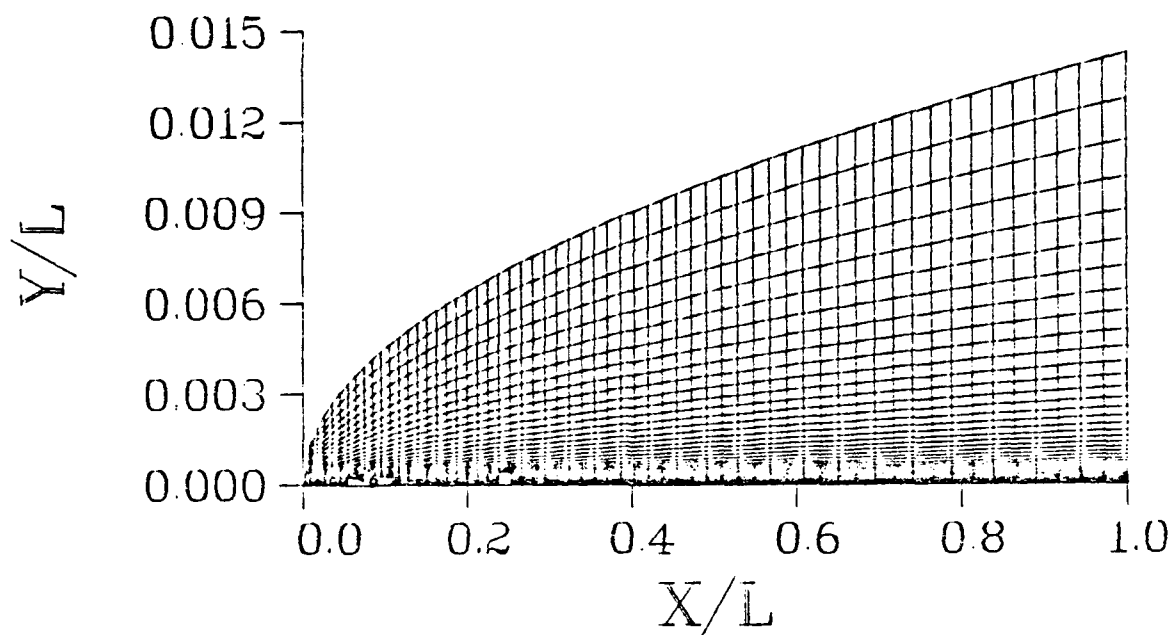

Figure 2.1. Dorodnitsyn Fixed Grid

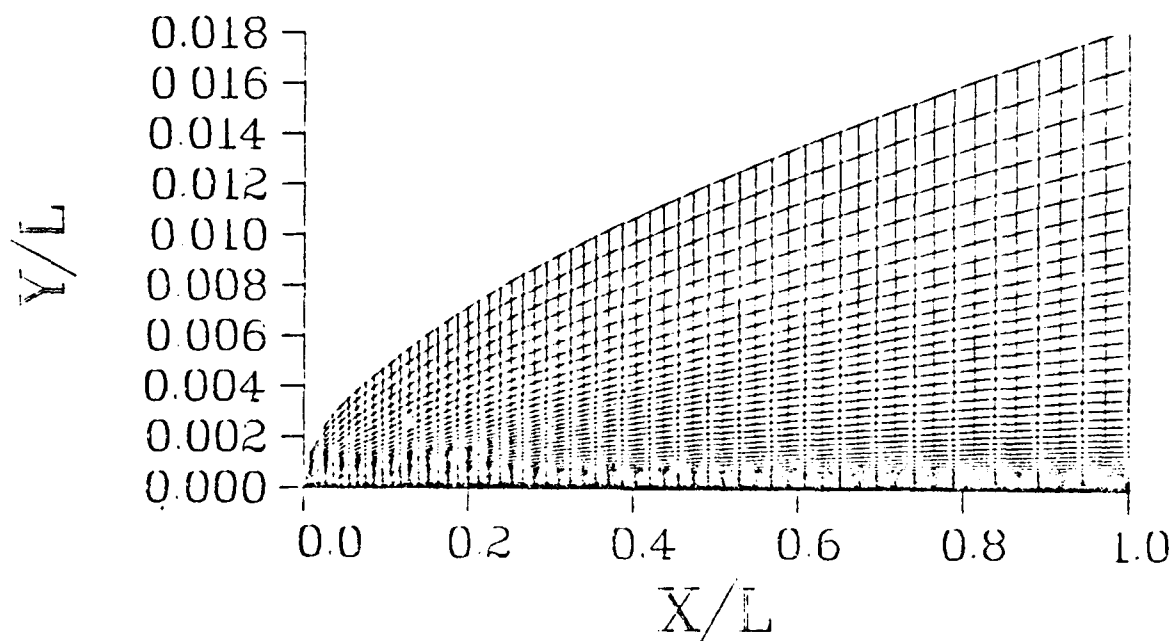

Figure 2.2. Physical Grid

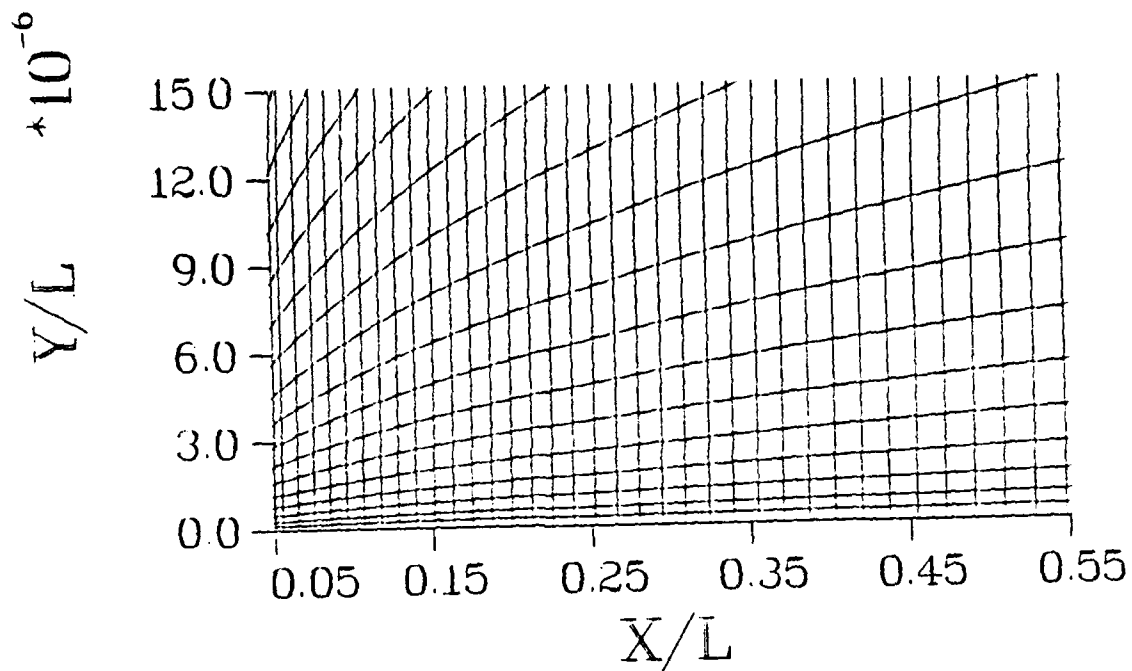

Figure 2.3. Dorodnitsyn Fixed Grid - Expanded View

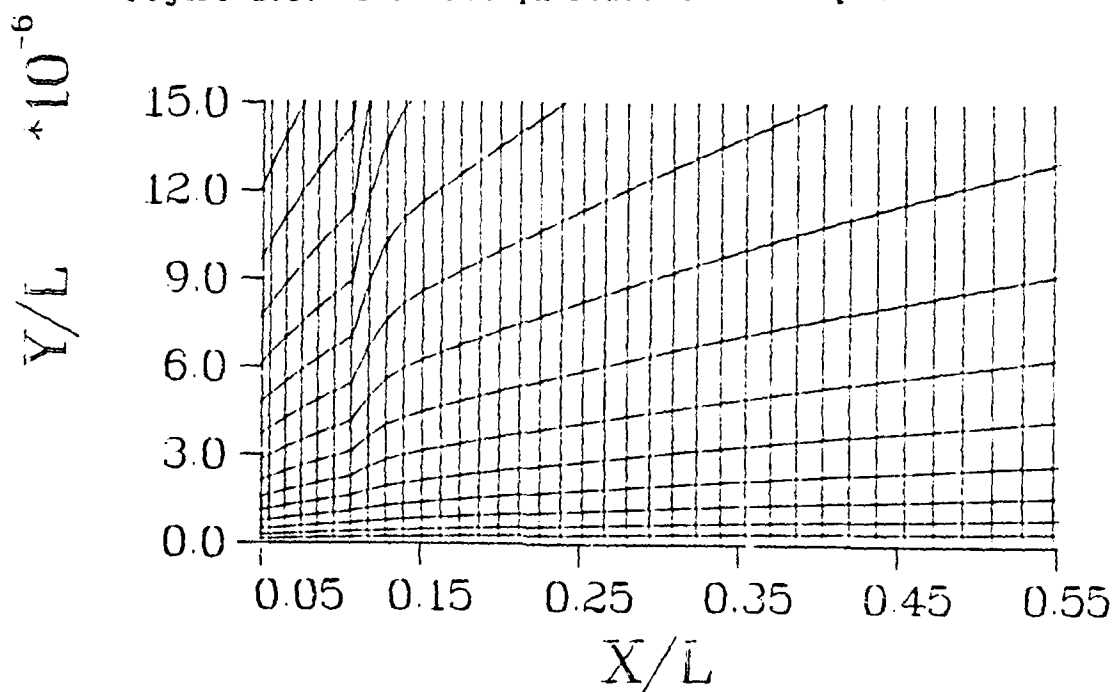

Figure 2.4. Physical Grid - Expanded View

where J is the Jacobian of the transformation,

$$J = X_\xi Y_\eta - Y_\xi X_\eta \quad (2.35)$$

The terms X_ξ , X_η , and Y_η are determined using finite differences. As in the original program, X does not change in the η direction so $X_\eta = 0$. The Y_ξ metric is determined differently than in Lange's thesis. Hodge (21) developed an analytical metric

$$Y_\xi = \frac{0.5 Y}{X_\xi X} \quad (2.36)$$

which increases the code's applicability to also include variable X step sizes. Calculating the Y_ξ metric analytically near the leading edge and then using a numerical solution for the remaining points downstream of the leading edge avoids the large leading edge error as found by Lange (34:27). The numerical differencing is the same as described in Lange's thesis. Hodge (21) further modified the program to accept as an input the point from the leading edge at which the program switches from the analytic to the numerical calculation of the Y_ξ metric.

2.3.3 Numerical Method

The unsteady two-dimensional boundary layer equations are solved numerically by using an implicit finite difference scheme because it is unconditionally stable according to linear theory. The governing equations are first nondimensionalized, then transformed by the Dorodnitsyn transformation. Finally, they are then

transformed from the X - Y plane to the $\xi - \eta$ computational plane.

Once the equations are transformed to the $\xi - \eta$ plane, the first order spatial derivatives in the momentum and energy equations are differenced using three point upwind differencing. This differencing scheme guarantees diagonal dominance and is second order accurate in the computational plane. The time derivative is differenced using a two point backward scheme which implies it is only first order accurate in time. The second derivatives are approximated with second order accurate central differencing. Similar terms are then combined.

2.4 Modifications to Original Program

The modifications to the original laminar program that exist in the turbulent boundary layer code are explained in this section in detail. A copy of the turbulent boundary layer code is listed in Appendix C.

The unsteady two-dimensional boundary layer equations have been time and mass-weighted averaged, non-dimensionalized, and transformed using the Dorodnitsyn transformation. The governing equations are then transformed from the X - Y plane to the $\xi - \eta$ computational plane. The continuity, x-momentum, and energy equations (2.30), (2.31), and (2.33) become

continuity

$$\xi \frac{\partial U}{\partial \xi} + \eta \frac{\partial U}{\partial \eta} + \eta \frac{\partial V}{\partial \eta} = 0 \quad (2.37)$$

x-momentum

$$\begin{aligned} \bar{U}_t + \bar{U} \left[\bar{U}_\xi \xi_X + \bar{U}_\eta \eta_X \right] + \bar{V} \bar{U}_\eta \eta_Y \\ = \eta_Y \left[\left[\mu + \mu_T \right] \varphi \left[\bar{U}_\eta \eta_Y \right] \right] \eta \frac{1}{Re} \end{aligned} \quad (2.38)$$

energy

$$\begin{aligned} \bar{H}_t + \bar{U} \left[\bar{H}_\xi \xi_X + \bar{H}_\eta \eta_X \right] + \bar{V} \bar{H}_\eta \eta_Y = \frac{1}{\varphi} \bar{P}_t \\ + \left[\frac{\varphi}{Re} \left[\frac{\mu}{Pr} + \mu_T / Pr \right] \bar{H}_\eta \eta_Y \right] \eta_Y \\ + \left[\frac{\varphi}{Re} \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr \right] \right] \eta_Y (1/2 \bar{U}^2) \eta \right] \eta_Y \end{aligned} \quad (2.39)$$

On a stationary flat plate, the pressure gradients in the normal direction are zero from the Y-momentum equation eqn (2.32). The pressure gradient in the streamwise direction has been assumed to be zero since any shock-boundary layer interaction is ignored. Now that the equations have been transformed to the $\xi - \eta$ plane, the derivatives are finite differenced similar to the original program (cf. section 2.3). The equations for the x-momentum and the energy equation (2.38) and (2.39) become,

Momentum

$$\begin{aligned}
 U_{i,j}^n = & \left[U_{i,j}^{n-1} + 2\bar{\epsilon}_X \bar{U} \Delta t U_{i-1,j}^n - .5 \bar{\epsilon}_X \bar{U} \Delta t U_{i-2,j}^n \right. \\
 & - .5 \left[\bar{\eta}_X \bar{U} \Delta t + \bar{\eta}_Y \tilde{V} \Delta t \right] U_{i,j-2}^n \\
 & + \left[2\bar{\eta}_X \bar{U} \Delta t + 2\bar{\eta}_Y \tilde{V} \Delta t + \bar{\eta}_Y \frac{\Delta t}{Re} \left[\rho \left[\mu + \mu_T \right] \right]_{j+1/2} \bar{\eta}_Y \right] U_{i,j-1}^n \\
 & \left. + \left[\bar{\eta}_Y \frac{\Delta t}{Re} \left[\rho \left[\mu + \mu_T \right] \right]_{j+1/2} \bar{\eta}_Y \right] U_{i,j+1}^n \right] / UCOEFF
 \end{aligned}$$

(2.40)

Energy

$$\begin{aligned}
 H_{i,j}^n = & \left[H_{i,j}^{n-1} + 2\bar{\epsilon}_X \bar{U} \Delta t H_{i-1,j}^n - .5 \bar{\epsilon}_X \bar{U} \Delta t H_{i-2,j}^n + \frac{1}{\bar{\rho}} dP \right. \\
 & - .5 \left[\bar{\eta}_X \bar{U} \Delta t + \bar{\eta}_Y \tilde{V} \Delta t \right] H_{i,j-2}^n \\
 & + \left[2\bar{\eta}_X \bar{U} \Delta t + 2\bar{\eta}_Y \tilde{V} \Delta t + \bar{\eta}_Y \frac{\Delta t}{Re} \left[\rho \left[\mu/Pr + \mu_T/Pr \right] \right]_{j-1/2} \bar{\eta}_Y \right] H_{i,j-1}^n
 \end{aligned}$$

$$\begin{aligned}
& + q_Y \frac{\Delta t}{Re} \left[\exp \left[\mu / Pr + \mu_T / Pr_T \right] \right]_{j+1/2} q_Y H_{i,j+1}^n \\
& + q_Y \frac{\Delta t}{2Re} \left[\exp \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j+1/2} q_Y U_{i,j+1}^n \\
& - \left[\exp \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j+1/2} q_Y \\
& + \left[\exp \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j-1/2} q_Y U_{i,j}^n \\
& + \left[\exp \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j-1/2} q_Y U_{i,j-1}^n \right] / UCoeff
\end{aligned}
\tag{2.41}$$

where

$$UCOEFF = 1 + \frac{3}{2} \xi \bar{U} \Delta t + \frac{3}{2} \eta \bar{U} \Delta t + \frac{3}{2} \eta \tilde{V} \Delta t$$

$$+ \eta_Y \frac{\Delta t}{Re} \left[\left[\rho \left[\mu / Pr + \mu_T / Pr_T \right] \right]_{j+1/2} \eta_Y \right. \\ \left. + \left[\rho \left[\mu / Pr + \mu_T / Pr_T \right] \right]_{j-1/2} \eta_Y \right] \quad (2.42)$$

Note that i and j are the node points in the $\xi - \eta$ plane, and n is the time level. The momentum and energy equations are nonlinear. To linearize the equations for the first iteration, the coefficients are lagged "in time". The coefficients in this program are based on the solution for U , V , and H at the previous time and same location for the first iteration, and subsequently from each previous iteration.

The linearization is the same as the original program. The calculation of the metrics also remain the same as developed by Hodge and Lange (cf. section 2.3.2). Once the momentum and energy equations are linearized, the equations can be written as:

Momentum

$$\begin{aligned}
 U_{i,j}^{s+1} = & \left[U_{i,j}^{n-1} + \frac{2\Delta t}{X_s} U_{i,j}^s U_{i-1,j}^{s+1} - \frac{\Delta t}{2X_s} U_{i,j}^s U_{i-2,j}^{s+1} \right. \\
 & - .5\Delta t \left[U_{i,j}^s \eta_X + \frac{1}{Y\eta} V_{i,j}^s \right] U_{i,j-2}^s \\
 & + 2\Delta t \left[\frac{1}{\left(\frac{Y_{i,j+1} - Y_{i,j-1}}{Y_{i,j} - Y_{i,j-1}} \right) \text{Re} \left(\frac{Y_{i,j} - Y_{i,j-1}}{Y_{i,j} - Y_{i,j-1}} \right)} \left[\rho \left[\mu + \mu_T \right] \right]_{j-1/2}} \right. \\
 & \left. + U_{i,j}^s \eta_X + \frac{1}{Y\eta} V_{i,j}^s \right] U_{i,j-1}^s \\
 & \left. + 2\Delta t \left[\frac{\left[\rho \left[\mu + \mu_T \right] \right]_{j+1/2}}{\left(\frac{Y_{i,j+1} - Y_{i,j-1}}{Y_{i,j+1} - Y_{i,j}} \right) \text{Re} \left(\frac{Y_{i,j+1} - Y_{i,j}}{Y_{i,j+1} - Y_{i,j}} \right)} U_{i,j+1}^s \right] \right] / \text{UCOEFF}
 \end{aligned} \tag{2.43}$$

Energy

$$H_{i,j}^{s+1} = \left[H_{i,j}^{n-1} + \frac{2\Delta t}{X_s} U_{i,j}^s H_{i-1,j}^{s+1} - \frac{\Delta t}{X_s} U_{i,j}^s H_{i-2,j}^{s+1} \right]$$

$$\begin{aligned}
& - .5 \Delta t \left[\begin{array}{c} s_n \\ U_{1,j} \end{array} q_X + \frac{1}{Y_n} \begin{array}{c} s_n \\ V_{1,j} \end{array} \right] H_{1,j-2} + \frac{1}{\bar{\rho}} dP \\
& + 2\Delta t \left[\frac{1}{\frac{(Y_{1,j+1} - Y_{1,j-1}) Re}{(Y_{1,j+1} - Y_{1,j})}} \left[\phi \left[\mu/Pr + \mu_T/Pr_T \right] \right]_{j-1/2} \right. \\
& \quad \left. + \begin{array}{c} s_n \\ U_{1,j} \end{array} q_X + \frac{1}{Y_n} \begin{array}{c} s_n \\ V_{1,j} \end{array} \right] H_{1,j-1} \\
& + 2\Delta t \left[\frac{1}{\frac{(Y_{1,j+1} - Y_{1,j-1}) Re}{(Y_{1,j+1} - Y_{1,j})}} \left[\phi \left[\mu/Pr + \mu_T/Pr_T \right] \right]_{j+1/2} \right] H_{1,j+1} \\
& + 2\Delta t \left[\frac{1}{\frac{(Y_{1,j+1} - Y_{1,j-1}) Re}{(Y_{1,j+1} - Y_{1,j})}} \left[\phi \left[\mu(1-1/Pr) + \mu_T \left[1-1/Pr_T \right] \right] \right]_{j+1/2} \right] \frac{s_n U_{1,j+1}}{2}
\end{aligned}$$

$$\begin{aligned}
& - \left[\frac{\left[\phi \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j+1/2}}{(Y_{1,j+1} - Y_{1,j})} \right] \\
& + \left[\frac{\left[\phi \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j-1/2}}{(Y_{1,j} - Y_{1,j-1})} \right] \left[\frac{U_n^2}{2} \right]_{1,j} \\
& + \left[\frac{\left[\phi \left[\mu(1 - 1/Pr) + \mu_T \left[1 - 1/Pr_T \right] \right] \right]_{j-1/2}}{(Y_{1,j} - Y_{1,j-1})} \right] \left[\frac{U_n^2}{2} \right]_{1,j-1} / \text{UCOEFF}
\end{aligned}
\tag{2.44}$$

where

$$\text{UCOEFF} = 1 + \frac{3}{2} \frac{U_n}{X_e} \Delta t + \frac{3}{2} \frac{U_n}{1,j} \frac{\eta}{X} \Delta t + \frac{3}{2} \frac{V_n}{Y_e} \Delta t$$

$$\begin{aligned}
& + \frac{2\Delta t}{(Y_{1,j+1} - Y_{1,j-1}) \text{Re}} \left[\frac{\left[\varphi \left[\mu/Pr + \mu_T/Pr_T \right] \right]_{j+1/2}}{(Y_{1,j+1} - Y_{1,j})} \right. \\
& \quad \left. + \frac{\left[\varphi \left[\mu/Pr + \mu_T/Pr_T \right] \right]_{j-1/2}}{(Y_{1,j} - Y_{1,j-1})} \right] \quad (2.45)
\end{aligned}$$

and

$$\begin{aligned}
X_x &= (X_{1+1,j} - X_{1-1,j})/2 \\
Y_{\eta} &= (Y_{1,j+1} - Y_{1,j-1})/2 \\
\eta &= \frac{-0.5 Y}{X_x X Y_{\eta}} = - \frac{Y_x}{X_x Y_{\eta}} \\
[\varphi(\mu^*)]_{j+1/2} &= ([\varphi(\mu^*)]_{j+1} + [\varphi(\mu^*)]_j)/2 \\
[\varphi(\mu^*)]_{j-1/2} &= ([\varphi(\mu^*)]_j + [\varphi(\mu^*)]_{j-1})/2 \quad (2.46)
\end{aligned}$$

where

$$\mu^* = \mu/Pr + \mu_T/Pr_T$$

or

$$\mu^* = \mu(1 - 1/Pr) + \mu_T(1 - 1/Pr_T)$$

and s is the iteration level. These equations are then solved in the program using an extension of Thomas' algorithm.

2.4.1 Thomas' Algorithm

Thomas' algorithm (3:99) is a technique for rapidly solving a tridiagonal system of linear algebraic equations. It is important to note that in any tridiagonal elimination scheme, as is Thomas' algorithm, truncation errors can grow quickly if diagonal dominance is not maintained. However, the finite differencing methods used in this program guarantee the existence of diagonal dominance. A diagonally dominant system guarantees errors are not propagated (3:343). The scheme of the Thomas' algorithm is as follows. Given a system of equations, M is the matrix of coefficients, U is the vector of independent variables, and E is the vector of dependent variables.

$$M_{1,j-1} U_{j-1} + M_{1,j} U_j + M_{1,j+1} U_{j+1} = E_i \quad (2.47)$$

This system of equations is a tridiagonal system, ie, the matrix M has non-zero values only on the main diagonal and the lower and upper diagonal. The system of equations can be rewritten

$$\begin{bmatrix}
 d1 & a1 & 0 & 0 & 0 \\
 b2 & d2 & a2 & 0 & 0 \\
 \cdot & \cdot & \cdot & \cdot & \cdot \\
 0 & b_{JMAX-2} & d_{JMAX-2} & a_{JMAX-2} & 0 \\
 0 & 0 & b_{JMAX-1} & d_{JMAX-1} & a_{JMAX-1} \\
 0 & 0 & 0 & b_{JMAX} & d_{JMAX}
 \end{bmatrix}
 \begin{bmatrix}
 U1 \\
 U2 \\
 \vdots \\
 U_{JMAX-2} \\
 U_{JMAX-1} \\
 U_{JMAX}
 \end{bmatrix}
 =
 \begin{bmatrix}
 E1 \\
 E2 \\
 \vdots \\
 E_{JMAX-2} \\
 E_{JMAX-1} \\
 E_{JMAX}
 \end{bmatrix}
 \quad (2.48)$$

Thomas' algorithm works by eliminating the "b" diagonal and then solving for the U vector beginning at the Jmax location and stepping backwards. After the "b" diagonal is eliminated, the new values of the "d" and "a" diagonal are computed by

$$d_j = d_j - \frac{b_j a_{j-1}}{d_{j-1}} \quad (2.49)$$

$$a_j = a_j \quad (2.50)$$

$$e_j = e_j - \frac{b_j e_{j-1}}{d_{j-1}} \quad (2.51)$$

The values for U may be obtained now by back substitution,

$$U_{Jmax} = \frac{e_{Jmax}}{d_{Jmax}} \quad (2.52)$$

$$U_j = \frac{e_j - a_j U_{j+1}}{d_j} \quad \text{for } j = Jmax-1, Jmax-2, \dots, 1 \quad (2.53)$$

When examining the governing equations for the momentum and energy equation (2.43) and (2.44), it can be seen that this particular system of equations is not a tridiagonal, but rather a penta-diagonal. An example of this penta-diagonal matrix can be seen in eqn (2.54).

The existence of the fourth or fifth diagonal depends on the sign of the V velocity. If the velocity is positive, the velocity gradients are backward differenced, and an $i, j-2$ term, "f" diagonal in eqn (2.54), will appear. If the velocity is negative the velocity gradients are forward differenced, and an $i, j+2$ term, "c" diagonal in eqn (2.54), will appear.

$$\begin{bmatrix}
 d1 & a1 & c1 & 0 & 0 & 0 \\
 b2 & d2 & a2 & c2 & 0 & 0 \\
 f3 & b3 & d3 & a3 & c3 & 0 \\
 \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
 0 & fJMAX-2 & bJMAX-2 & dJMAX-2 & aJMAX-2 & cJMAX-2 \\
 0 & 0 & fJMAX-1 & bJMAX-1 & dJMAX-1 & aJMAX-1 \\
 0 & 0 & 0 & fJMAX & bJMAX & dJMAX
 \end{bmatrix} \quad (2.54)$$

This situation is handled in the program differently depending on the sign of the velocity. If the velocity is positive, the $i, j-2$ term is a known value at the previous iteration and included in the e vector and the matrix is solved as a tridiagonal system of equations. If the velocity is negative, the $i, j+2$ term is an unknown and the

matrix is solved as a quad-diagonal. Eqns (2.50) and (2.53) need to be redefined if a quad-diagonal exists. The recursion formulas become:

$$a_j = a_j - \frac{b_j c_{j-1}}{d_{j-1}} \quad (2.55)$$

$$c_j = c_j \quad (2.56)$$

and then for the back substitution,

$$U_{J_{\max}-1} = \frac{e_{J_{\max}-1} - a_{J_{\max}-1} U_{J_{\max}}}{d_{J_{\max}-1}} \quad (2.57)$$

$$U_j = \frac{e_j - a_j U_{j+1} - c_{j+1} U_{j+2}}{d_j} \quad (2.58)$$

where $j = J_{\max}-2, J_{\max}-3, \dots, 1$. This modification of the use of Thomas' algorithm should improve the efficiency of the program, relative to the efficiency using the optimized successive over-relaxation. A comparison of execution time was completed and the results are shown in a later section.

2.4.2 Turbulence Model

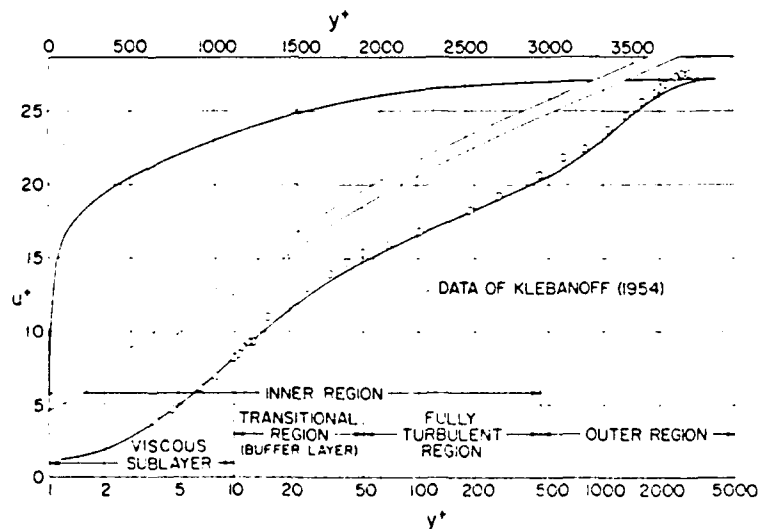

Turbulent boundary layer flow is divided into two regions: an inner region, and an outer region. The inner region is further subdivided into three regions, the viscous sublayer, the transitional region, and the fully turbulent region. The inner region of a turbulent boundary layer is much smaller than the outer region, with a thickness of about 10 to 20 % of the entire boundary layer thickness. An

example of these regions are illustrated in Figure 2.5. To deal with the different regions, some special parameters (7:95) have been defined. They are:

$$U^+ = \left(\frac{\tau_w}{\rho_w} \right)^{1/2} \quad (2.59)$$

$$Y^+ = \frac{Y U^+ \rho_w}{\mu_w} \quad (2.60)$$

$$U^+ = U / U^+ \quad (2.61)$$

Semilogarithmic and linear plots of mean velocity distribution across a turbulent boundary layer with zero pressure gradient. The linear plot is included to show a true picture of the thickness of various portions. (7:94)

Figure 2.5. Turbulent Boundary Layer Regions

If $Y^+ < 10.0$, the region is typically considered to be the

viscous sublayer. If $10.0 < Y^+ < 500.0$, the region is typically defined as the rest of the inner region. If $Y^+ > 500.0$, the region is typically the outer region. These limits are very dependent upon the specific flow conditions.

In the viscous sublayer, molecular viscosity is assumed to be dominant over the turbulent viscosity, so that the turbulence viscosity approaches zero in this region. For the rest of the inner region, two models will be considered in this study; the Van Driest and Chapman models. In the outer region, the mixing layer model and Clauser's mixing length model have been included. The mixing length model has the turbulent length scale varying proportionately with the boundary layer thickness. Clauser's model has the turbulent viscosity varying proportionately with the kinematic displacement thickness. Clauser's model is recommended for compressible flow cases (7:120; 49:8), since it has been shown in several references to be more accurate.

Turbulence models center around the definition of the turbulent viscosity. Prandtl's Mixing Length Theorem states that the turbulent viscosity is related to two parameters: a turbulent length scale - called a mixing length, l , and the U velocity gradient in the normal direction.

$$\mu_T = \rho l^2 \left| \frac{\partial U}{\partial Y} \right| \quad (2.62)$$

The two models for the inner region mixing length; the Van Driest model and the Chapman model, will now be examined.

This will be followed by the two models for the outer region, the mixing layer model and Clauser's model.

2.4.2.1 Inner Region Van Driest Model

The Van Driest model for the mixing length for turbulent flow was developed by considering flow over an oscillating plate (Stokes flow). Van Driest modified Prandtl's mixing length equation so that

$$l\# = KY\# [1 - \exp (-Y\#/A\#)] \quad (2.63)$$

where K is von Karman's constant. K is nominally 0.41, but can be changed in the program for each case since K is an input. If the turbulent viscosity, eqn (2.62) is rewritten,

$$\mu\# = \rho\# (KY\#)^2 L_m \left| \frac{\partial U\#}{\partial Y\#} \right| \quad (2.64)$$

where L_m can be called a new mixing length parameter defined by Van Driest (7:213-215) as

$$L_{m\text{ VD}} = [1 - \exp (-Y\#/A\#)]^2 \quad (2.65)$$

The $A\#$ defined originally by Van Driest is limited to incompressible turbulent boundary layers with negligible pressure gradient and zero mass transfer. Cebeci and Smith (7:215-217) include compressibility effects by adding a density ratio to the parameter $A\#$ so it becomes,

$$A\# = A \left(\frac{\rho\#}{\rho\#} \right) \left(\frac{\tau\#}{\tau\#} \right)^{-1/2} \left(\frac{\rho\#}{\rho\#} \right)^{1/2} \quad (2.66)$$

where $A = 26.0$.

If the definition for $Y\#$, eqn (2.60), is solved for $Y\#$ and substituted in eqn (2.65), $L_{m\text{ VD}}$ can be rewritten as

$$L_{m_{VD}} = (1 - \exp[-(Y/A)^+])^2 \quad (2.67)$$

Now that the model has been defined, it is of interest to determine what kind of behavior the Van Driest's mixing length parameter contributes to the Reynold's stress or turbulent viscosity near the wall. If the series expansion for $\exp(-Y\#/A\#)$ near the wall, is

$$\exp(-Y/A) = \sum_{n=0}^{\infty} \frac{(-1)^n}{n!} (Y/A)^n = 1 - Y/A + \text{H.O.T.} \quad (2.68)$$

(where H.O.T. means higher order terms) and is substituted into eqn (2.65), it can be seen that

$$L_{m_{VD}} = (Y\#/A\#)^2 + \text{H.O.T.} \quad (2.69)$$

where only the first term is retained since it determines the behavior of the function. Substituting this equation for $L_{m_{VD}}$ back into equation (2.64) one obtains

$$\mu_T = \phi\# K^2 \frac{Y\#^4}{A\#^2} \left| \frac{\partial U\#}{\partial Y\#} \right| \quad (2.70)$$

Therefore, the Van Driest model gives the turbulent viscosity fourth order behavior in $Y\#$.

2.4.2.2 Inner Region Chapman Model

The motivation that Chapman had in deriving a new mixing length model arose from an analysis of oscillating shear flow over an infinite plate; recall Van Driest studied flow over an oscillating plate. Using only the continuity

equation and Taylor series expansions, Chapman, and Reichardt (9:7) earlier, showed that the leading term of the Reynolds stress is proportional to Y^3 . Therefore, the turbulent viscosity should also be proportional to Y^3 .

Prandtl's Mixing Length equation with Van Driest's initial modification, eqn (2.63), is used in the Chapman model. However, the mixing length for turbulent flow needed in eqn (2.64) as given by Chapman (9:8) is

$$L_m = \left[1 - 2 \cos \beta \exp(-\beta) + \exp(-2\beta) \right]^{1/2} \quad (2.71)$$

where $\beta = Y^+ / AOS$, and AOS is usually 111.0 for incompressible flow. [Reference (9) has a typographical error, eqn (2.71) is correct (8)]. For this analysis it was assumed that the same density ratio compressibility factor, as developed by Cebeci and Smith for the Van Driest model, could also be included in AOS to account for compressibility effects.

$$AOS = AOS^+ \left(\frac{\rho}{\rho_w} \right)^{1/2} \quad (2.72)$$

where $AOS^+ = 111.0$ and β becomes

$$\beta = \frac{Y^+}{AOS} \quad (2.73)$$

To determine the type of behavior the Chapman model contributes to the turbulent viscosity, the series representation of the cosine function and the exponential function,

$$\cos(\beta) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} (\beta)^{2n} = 1 - .5\beta^2 + \text{H.O.T.} \quad (2.74)$$

$$\exp(-\beta) = \sum_{n=0}^{\infty} \frac{(-1)^n}{n!} \beta^n = 1 - \beta + \text{H.O.T.} \quad (2.75)$$

$$\exp(-2\beta) = \sum_{n=0}^{\infty} \frac{(-1)^n}{n!} (2\beta)^n = 1 - 2\beta + \text{H.O.T.} \quad (2.76)$$

are substituted into equation (2.71) so that L_m can be rewritten in the form

$$L_m = [1 - 2(1 - .5\beta^2 + \dots)(1 - \beta + \dots) + (1 - 2\beta + \dots)]^{1/2} \quad (2.77)$$

$$L_m = [\beta^2 + \text{H.O.T.}]^{1/2} \approx \beta + \text{H.O.T} \quad (2.78)$$

Substituting the leading term of eqn (2.78) into the equation for the turbulent viscosity, eqn (2.64), one obtains

$$\frac{\mu}{T} = \frac{\phi}{AOS} K^2 Y^{\#3} \left| \frac{\partial U}{\partial Y} \right| \quad (2.79)$$

Therefore, it can be seen that Chapman developed his model to achieve third order behavior in $Y^{\#}$ for the turbulent viscosity.

The Van Driest and Chapman mixing length theories will both be used in the program and the differences between their results examined in a later section.

2.4.2.3 Outer Region Mixing Length Model

In the outer region, the flow is very different than the inner region, so a new scaling for the mixing length is

needed. Again, using Prandtl's mixing length theorem, the applicable equation for turbulent viscosity is equation (2.62). During the calculations of the mixing length $l\#$, when the parameter $l\#$ becomes equal to $.089\delta\#$, the equation for $l\#$ is changed to

$$l_{o\#} = 0.089 \delta\# \quad (2.80)$$

This new equation for $l\#$, eqn (2.80) (3:223), insures that the inner and the outer regions will be piecewise continuous in the turbulent length scale and the turbulent viscosity.

2.4.2.4 Outer Region Clauser Model

The Clauser model (3:225) assumes the turbulent viscosity is proportional to the kinematic viscosity, $\delta\#$. The equation for the turbulent viscosity for the Clauser model is:

$$\mu_T\# = \alpha\# \rho\# U_e\# |\delta\#| \quad (2.81)$$

where $\alpha\#$ accounts for low Reynolds number effects. For Reynold's numbers greater than 5000,

$$\alpha\# \approx 0.0168 \quad (2.82)$$

and the kinematic displacement thickness is defined by

$$\delta\# = \int_0^{\infty} \left[1 - \frac{U\#}{U_e\#} \right] dy\# \quad (2.83)$$

For the cases run in this study, the edge velocity is equivalent to the freestream velocity, so $U_e\#$ is used in eqn (2.83). The integral is evaluated using a trapezoidal rule

with U averaged about the $j-1/2$ point prior to the integration. When the Clauser's model is used in the program, the switch between the inner region and the outer region occurs when $\mu_T(\text{outer}) = \mu_T(\text{inner})$ so that the turbulent viscosity is piecewise continuous between the two regions.

2.4.2.5 Intermittency

As the edge of the boundary layer is approached in the outer region, the turbulence becomes intermittent; that is, only a fraction, σ , of the time the flow is turbulent. Without a factor to account for this intermittency, the amount of turbulence calculated to be present in the outer region would be overpredicted. The intermittency factor is defined by an error function (7:110) but is approximated by (50:4)

$$\sigma = [1 + 5.5 (Y^\#/\delta^\#)^6]^{-1} \quad (2.84)$$

The intermittency parameter is introduced into the model by multiplying μ_T by σ .

2.4.3 Transition Model

The transition model bridges the gap between laminar flow and fully turbulent flow. One such model (18:29) considers the transition region, and introduces a transition parameter that varies from 0, the edge of the laminar region, to 1, the beginning of the fully turbulent region. This transition parameter multiplies the turbulent

viscosity. Therefore, only a fraction of the turbulent viscosity is added to the governing equations, depending on the position of the flow in the transition region.

The transition parameter, r , is defined as (18:29)

$$r = 1 - \exp(-.412 \theta^2) \quad (2.85)$$

where θ is the normalized streamwise coordinate in the transition region. θ is defined by

$$\theta = \frac{x - x_{T,I}}{\bar{x}} \quad \text{where} \quad x_{T,I} \leq x \leq x_{T,F} \quad (2.86)$$

with $x_{T,I}$ being the location of the beginning of transition and $x_{T,F}$ is the final location of transition, or the beginning of the fully turbulent region. The x is the location that is being analyzed. The measure of the extent of the transition region is \bar{x} where it is defined by

$$\bar{x} = x|_{r=3/4} - x|_{r=1/4} \quad (2.87)$$

Usually \bar{x} is allowed to vary until agreement with experimental data is reached. The use of this model insures a smooth transition from laminar to fully turbulent flow.

2.4.4 Heat Transfer and Viscosity

The original program references the heat transfer calculations to reference conditions. These references are not useful for turbulent flow data. To examine the turbulent heat transfer data on a flat plate, it is customary to compare the Stanton number with the local Reynold's number, Re_x , as shown in Figure 2.6. The Stanton number is defined as

$$St = \frac{HC}{cp\phi-U_{\infty}} \quad (2.88)$$

with the heat transfer coefficient being defined as

$$HC = \frac{q}{T_{AW} - T_{\infty}} \quad (2.89)$$

The local Reynold's number is defined as

$$Rex = \frac{\rho U_{\infty} x}{\mu} \quad (2.90)$$

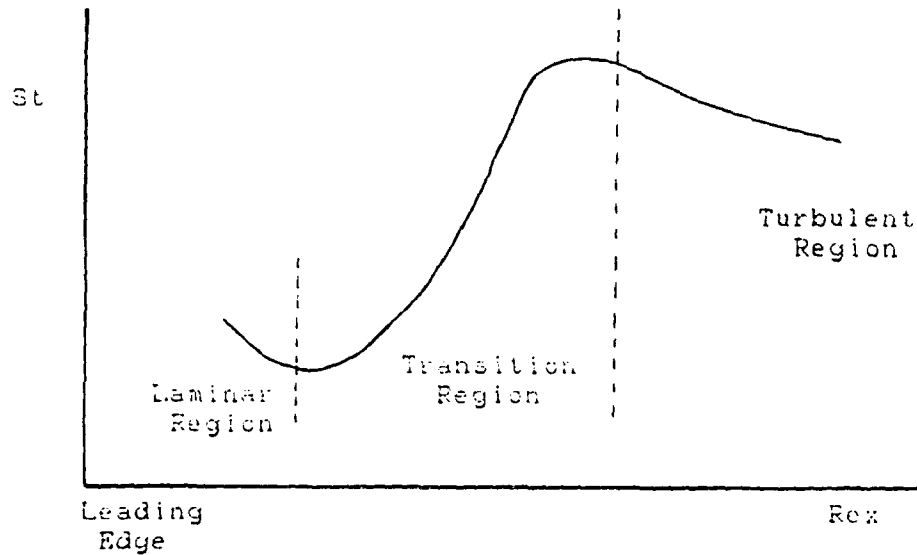

Figure 2.6. Heat Transfer on a Flat Plate

where x is the position on the plate where the Stanton number was obtained. If r is the recovery factor, the adiabatic wall temperature is defined as

$$T_{AW} = T_o [1 + .5 r (\gamma - 1) M_{\infty}^2] \quad (2.91)$$

The recovery factor in this study is defined as

$$r = Pr^{1/2} \quad \text{for laminar flow} \quad (2.92)$$

$$r = Pr^{1/3} \quad \text{for turbulent flow} \quad (2.93)$$

The transition model is used to vary the value of the recovery factor in the transition region. The value of the Prandtl number is 0.72.

In turbulence models, a turbulent Prandtl number is defined as

$$Pr_T = \mu_T c_p / k_T \quad (2.94)$$

and its nominal value is 0.90. The turbulent Prandtl number is a counterpart of the molecular Prandtl number to take into account the turbulent energy transport. However, the turbulent Prandtl number is used as a tool to obtain the turbulent conductivity, k_T . Since the turbulent Prandtl number and the heat capacity for constant pressure are both constants, it is interesting to note that

$$k_T \approx \mu_T \quad (2.95)$$

This says that the diffusion of the turbulent energy is directly related to the turbulent viscosity.

The local skin friction coefficient, c_f , is calculated by the program using (7:28)

$$c_f = \frac{2 \tau_w}{\rho U_\infty^2} \quad (2.96)$$

The theoretical skin friction coefficient for incompressible flow on a smooth flat plate is given by (7:187)

$$c_f = 0.664 (Re_x)^{1/2} \quad (2.97)$$

The viscosity is calculated throughout the program using Keyes viscosity equation, which is

$$\mu = \frac{2.32 \times 10^{-8} T^{1/2}}{1 + \frac{220}{T \times 10^9}} \quad \frac{\text{lb sec}}{\text{ft}^2} \quad (2.98)$$

where T is in degrees Rankine. Keyes viscosity law is more accurate (34:5) in the temperature range encountered in hypersonic wind tunnels than the popular Sutherland's viscosity law. In hypersonic tunnels, the static freestream temperature is generally between 30°R and 200°R, which is below 300°R, the demonstrated range of applicability of Sutherland's law.

2.5 Program Verification

The thesis computer code is verified by comparison of its results to experimental data and another computer code. The experimental data was obtained from several sources, and will be described later in each of the pertinent sections. The other computer code, hereafter called the ITRACT computer code, was developed by the Hypersonic Research Laboratory at Wright-Patterson Air Force Base. The code is a steady state compressible boundary layer code using the Van Driest eddy viscosity turbulence model (49).

2.5.1 Incompressible Laminar

The program inputs used for comparison against incompressible laminar flow over a flat plate (Blausius' solution) are $M_\infty = .05$ and $T_\infty = 530^\circ \text{R}$. The Y_w metric was calculated analytically over the entire plate. In Figure 2.7, the Blasius solution (46:42) for the velocity is plotted against the numerical solution for the program in laminar flow. The computer results fall almost directly on top of the theoretical results. In Figure 2.8, the ratio of the numerical skin friction coefficient to the theoretical skin friction coefficient is plotted against $x^\# / L^\#$. Since the results are very nearly a constant 1.0, the computer results almost exactly match the theoretical results.

At this Mach condition, the flow is incompressible and laminar so the Dorodnitsyn transformation and turbulence model are still unverified. However, the Thomas algorithm has been verified to be correct.

2.5.2 Incompressible Turbulent Isothermal

It is necessary to verify the validity of the turbulence model. This is done by comparing its results with that of experimental data. The data are taken from a NASA memorandum (44:24). The probable errors in the local Stanton numbers is $\pm 3\%$, and the probable errors in the local Reynolds number is $\pm 1\%$ (44:17). The NASA reference calculated the heat transfer coefficient using

$$HC = \frac{q}{T_w - T_\infty} \quad (2.99)$$

The ITRACT computer code calculated HC using

$$HC = \frac{q}{T_o - T_w} \quad (2.100)$$

The thesis computer code calculates HC using

$$HC = \frac{q}{T_{AW} - T_w} \quad (2.101)$$

The two computer codes were first modified so that the heat transfer coefficient was calculated by the eqn (2.99) which was used by the NASA reference. The data from the three different sources could now be compared. The Y_δ metric in the thesis computer program was calculated analytically over the entire plate. Note that the computer code actually calculates compressible flow conditions, but the density variations are on the order of 1% .

Figure 2.9 shows the results of the comparison when the Van Driest model is used for the inner region, and Clauser's model is used for the outer region. The ITRACT computer solution is approximately 20% lower than the experimental data, while the thesis computer solution is approximately 10% lower than the experimental data. This difference could be due to the value of the empirical constants used in the turbulence models, and also truncation errors. However, the thesis code does an adequate job in predicting heat transfer for incompressible turbulent flows.

2.5.3 Incompressible Turbulent Nonisothermal

The thesis code can now be verified using experimental data for incompressible turbulent flow with a nonisothermal wall, or thermal mismatch of approximately 20°F. The data are obtained from a NASA memorandum (45:27). The NASA reference calculates the heat transfer coefficient as shown in eqn (2.99). Again the thesis computer code was modified so that the calculation of the heat transfer coefficient was consistent with the experimental data. The Y_* metric in the thesis computer program was calculated analytically over the entire plate.

When the Van Driest model is used in the inner region and Clauser's model is used in the outer region, Figure 2.10 shows the results of the the comparison. The thesis solution is very close to the experimental data.

2.5.4 Compressible Turbulent Isothermal

The turbulence model and the Dorodnitsyn transformation need to be validated for compressible flow. This will be done by comparing the code to experimental shock tube data of compressible turbulent flow. The data are obtained from a NASA Contractor Report (4:131). The report verifies that the shock tube data agree with perfect gas results to within 3 %.

The experimental data shows a spike in the heating at the beginning of transition. This spike is characteristic of shock tube data. Transition in a shock tube is first

indicated by a series of spikes in the heat transfer data. These spikes are associated with "turbulent bursts" created at the edge of the viscous sublayer (23:6,12). The experimental data also calculates the heat transfer coefficient differently than the thesis computer program. The reference calculates the heat transfer coefficient using

$$HC = \frac{q_{cp}}{H_o - H_w} \quad (2.102)$$

Assuming constant heat capacity, the ITRACT and thesis codes were modified to be consistent with the experimental data.

When the Van Driest model is used for the inner region and Clauser's model is used for the outer region, Figure 2.11 shows the results of the comparison. The ITRACT code for the fully turbulent case is approximately 20% higher than the experimental data. The thesis code is 10% higher than the experimental data, but does model the peak heating at the end of transition very well. Both codes do an excellent job in predicting the laminar portion of the curve.

Figure 2.12 shows a comparison between all the models used in this study. Four cases were examined: Van Driest / Clauser, Van Driest / Mixing Length, Chapman / Clauser, and Chapman / Mixing Length. The inner region models, Van Driest and Chapman, produce results to within 1% of each other, with Chapman giving slightly lower results. This indicates that the argument between the models, the Y⁴

versus Y^3 dependence on the turbulent viscosity is mainly an academic discussion for this case. The outer region models, mixing length and Clauser, also produce similar results, with the mixing length model giving 1.5% higher results than Clauser's model.

2.6 Results of Computational Effort

2.6.1 Decrease in Computer Time

A comparison between the original program with the optimized successive over-relaxation method and the modified program with the Thomas algorithm was completed for laminar flow. Table (2.1) gives the results of the comparison. NT is the number of time steps, DT was the temporal increment in artificial units, and the maximum error allowed was EPS. For these runs, NT = 10, and DT = 1000. As the maximum error allowed increases, the difference between the two algorithms decreases, so there would be no advantage to using the Thomas algorithm versus optimized successive over-relaxation when high accuracy is not important. However, it is evident for the error criteria specified in these cases, the Thomas algorithm is more efficient for solving this particular differencing scheme, especially for grids with a larger number of points.

Table 2.1. Comparison of SOR and Thomas Algorithm

	SOR (CPU Seconds)	Thomas (CPU Seconds)
-5 EPS = 10 61x30 Grid	20	16
-6 EPS = 10 61x30 Grid	32	21
-5 EPS = 10 61x59 Grid	297	35

2.6.2 Laminar

The thesis program is excellent in predicting the flow properties of incompressible laminar flows. The program verification of the U velocity and skin friction coefficient showed the results were nearly identical to the theoretical results.

2.6.3 Turbulence

The thesis program predicts the heat transfer of incompressible and compressible turbulent flows very well. The thesis program results were approximately 10% different than the experimental data. This 10% error could perhaps be due to truncation error. The use of an optimized grid could probably improve the results. However, the program accurately predicted the heat transfer results of the incompressible turbulent flow when a thermal mismatch of 20° was present. Comparisons of the inner region and outer region models showed very little difference between the results, with the Chapman model giving 1% lower results

compared to Van Driest, and the mixing length model giving
1.5% higher results compared to Clauser.

III. Experimental Effort

3.1 Introduction

The experimental effort consisted of the study of a blunt fin at incidence on a sharp nosed flat plate. The phenomena of interest was the areas of high heating on the expansion side of the blunt fin. The research consisted of three main phases:

Phase I: Calibration of the von Karman Institute H-3 wind tunnel to determine the extent of the uniform velocity jet.

Phase II: Study of the flow on a flat plate to determine the location of transition and turbulence.

Phase III: Study of the interaction flow on a flat plate on the expansion side of a blunt fin in laminar flow.

The flow studies include flow visualization techniques, such as oil flow, sublimation, shadowgraph, and liquid crystals, and then also quantitative thin film and coax gage heat transfer tests. Tests were completed at a Mach number of 6.0 at two Reynolds numbers, $0.844 \times 10^7 / m$ and $1.69 \times 10^7 / m$ which correspond to two reservoir pressures, 10 and 20 bars, respectively. DeGraef (14) had completed liquid crystal tests on this particular interaction flow at Mach 5.26, but only in turbulent flow.

3.2 H-3 Blowdown Wind Tunnel

This research was conducted in the VKI H-3 blowdown intermittent tunnel illustrated in Figure 3.1. The test gas is air and is supplied from a 40 bars compressor. The air is heated by a pebble bed, to avoid condensation of air components (principally nitrogen) occurring during the test (35:137). When condensation occurs, isentropicity is lost, and the test data can no longer be interpreted correctly. Daum and Gyarmathy (13:464) have developed a method to determine the minimum stagnation temperature which may be used to avoid condensation. For the test conditions in this study, their method gives a minimum stagnation temperature of 406°K. All the tests in this study were completed at a stagnation temperature of approximately 473°K. The tunnel uses an air ejector to evacuate the test chamber to ease startup conditions. The high pressure air in the reservoir is expanded in the axisymmetric nozzle giving a uniform free jet of Mach 6. The nozzle exit diameter is approximately 154 mm. The size of the uniform Mach 6 jet will be determined from the tunnel calibration.

There is a model injection system which is driven by a pneumatic mechanism. The test section contains a three degree of freedom (incidence angle, yaw angle, and axial position) traversing mechanism for the model and probe support.

HYPersonic TUNNEL H3

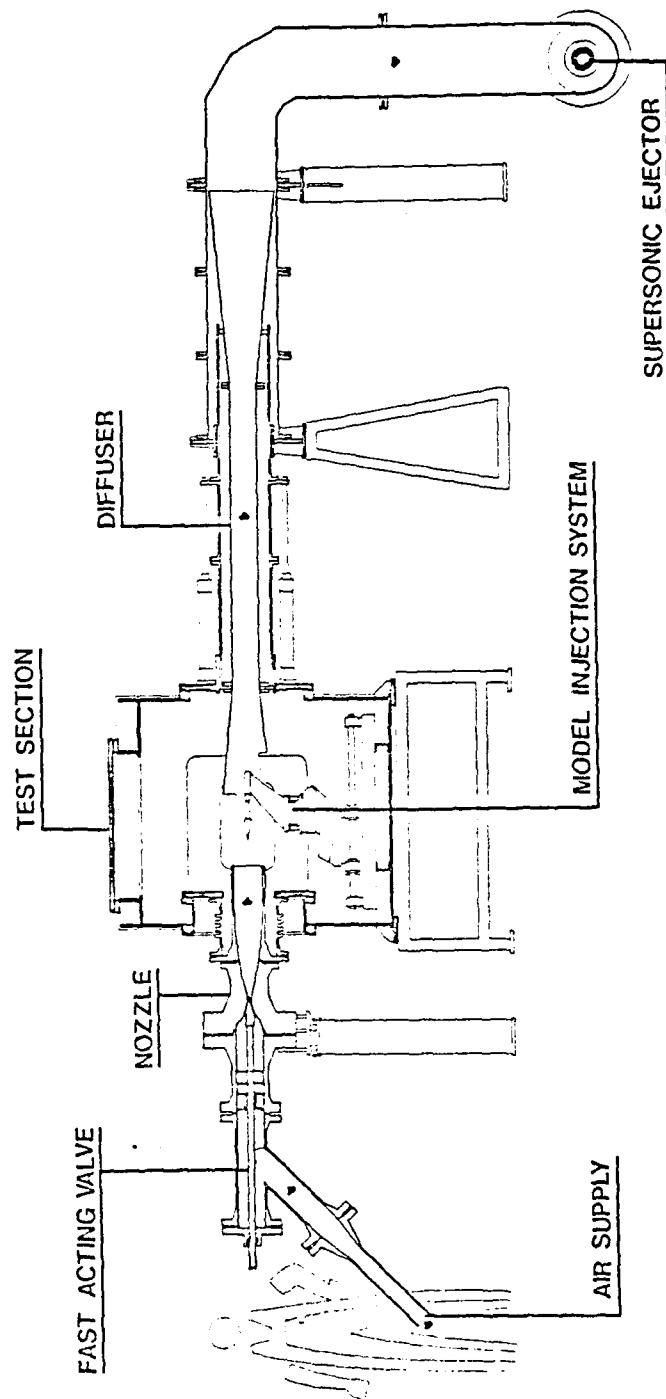

Figure 3.1. VKI H-3 Wind Tunnel

The reservoir chamber pressure can vary from 7 to 35 bars corresponding to a unit Reynold's number from 10^7 to 4×10^7 / meter. Running times up to five minutes are available. However, in order to reduce energy consumption, experiments usually have a short duration.

3.3 Calibration of the H-3 Wind Tunnel

3.3.1 Purpose

To determine the size of the flat plate model to construct, the scope of the Mach 6 uniform free jet must be determined. The first time the tunnel was calibrated was after its installation in 1970 (29). That previous calibration showed the existence of a small centerline disturbance and the slow streamwise growth of the outer shear layer. Details of the calibration procedure used and results obtained in this study are included in Appendix E.

3.3.2 Conclusions of Calibration

The results from this study also shows the presence of a slow growing shear layer and centerline disturbances. The experimental errors in the Mach number are less than .5%. The extent of the uniform flow has been obtained and the centerline Mach number variations have been shown to be within 2.2% of the mean flow in this uniform flow region. The streamwise flow at a radial distance of 39 mm from the centerline shows a slow rise in Mach number as the distances from the nozzle increases, from a mean Mach number of approximately 5.97 to 6.00. The streamwise flow at the

center of the tunnel also shows a rise in Mach number, but the rise is more dramatic. The rise is sudden between $x = 3.5$ mm and 53.5 mm, the mean centerline flow increases from an approximate Mach number of 5.89 to 6.04. Then, the rise is much slower, perhaps even becoming constant after $x = 143.5$ mm at a Mach number of 6.05.

From the calibration, the flow can be considered to be a uniform axisymmetric jet of Mach 6. The uniform flow has been determined to within ± 2 mm to be approximately 117 mm in diameter at the nozzle exit and it remains relatively constant until a distance of 103.5 mm downstream of the nozzle exit. The uniform flow then decreases to approximately 98 ± 2 mm in diameter at 143.5 mm downstream of the nozzle exit. Using the data from Table E.2, the region of uniform flow is sketched in Figure 3.2. The boundary of the uniform flow region beginning at the nozzle exit is interpolated to 143.5 mm behind the nozzle exit. After $x = 143.5$ mm, the region of uniform flow could be extrapolated to $x = 300$ mm. However, the region of uniform flow resulting from the extrapolation appears unrealistic. It is difficult to believe that the shear layer would grow as fast as the extrapolation indicated. This seems to indicate that there is not enough information available to draw a conclusion about the extent of the growth of the shear layer farther than the 143 mm after the nozzle exit. More calibration tests are required if tunnel models exceed

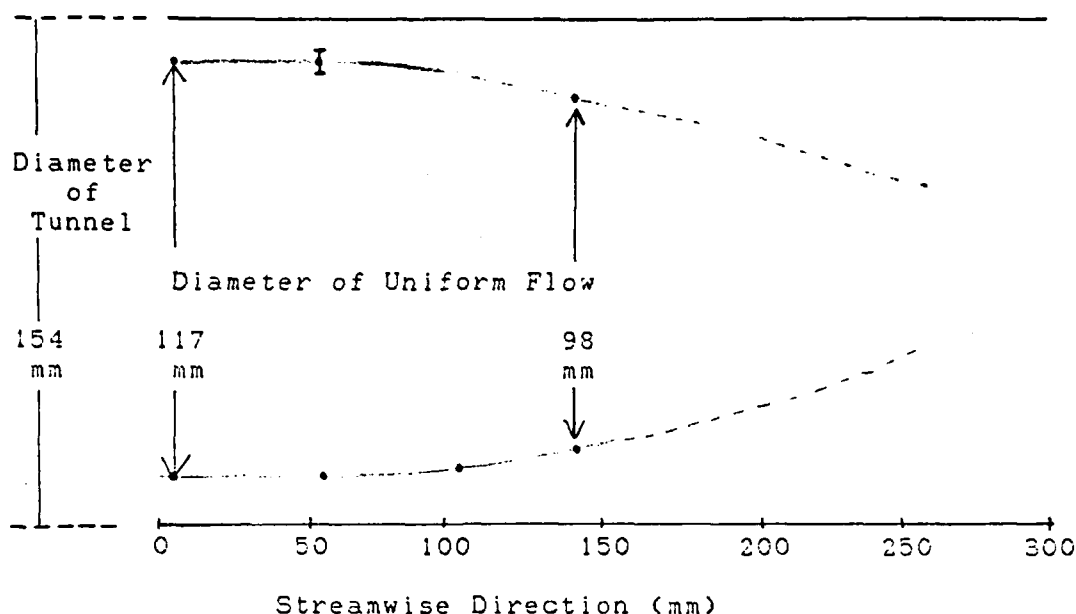

Figure 3.2. Sketched Regions of Uniform Flow

150 mm in length, but this would entail, not only conducting more tests, but designing a new pressure rake to avoid the occurrence of tunnel blockage.

3.4 Theory

3.4.1 Isentropic Flow Calculations

The static properties of the flow are calculated using isentropic flow relations. Since the reservoir total pressure and temperature are known, the static pressure and temperature can be obtained using these equations (35:53)

$$T = T_o (1 + .5(\gamma-1)M^2)^{-1} \quad (3.1)$$

$$P = P_o (1 + .5(\gamma-1)M^2)^{-[\gamma/(\gamma-1)]} \quad (3.2)$$

The static density can be computed using the perfect gas law

$$\rho = P/(RT) \quad (3.3)$$

where $R = 287.0 \text{ Nm/kg}^\circ\text{K}$ and is the gas constant for air.

The local speed of sound can be calculated using

$$a = (\gamma RT)^{1/2} \quad (3.4)$$

and the local velocity is $U = aM$. For viscosity, Keyes law is used, which is in foot-pound-second units

$$\mu_{\text{FPS}} = \frac{2.32 \times 10^{-8} T^{1/2}}{1 + \frac{220.0}{9/T} T \times 10} \quad (3.5)$$

μ has units of lb sec/ft^2 or slug/ft-sec with T in $^\circ\text{R}$.
FPS

The static temperature is converted initially from $^\circ\text{K}$ to $^\circ\text{R}$ using

$$^\circ\text{R} = (9/5) T^\circ\text{K} \quad (3.6)$$

The viscosity is then computed in units of lb sec/ft^2 using eqn (3.5) and converted to metric units of kg/m-sec when multiplied by a conversion factor

$$\mu = \mu_{\text{FPS}} (3.281 \text{ ft/m})(14.59 \text{ kg/slug}) \quad (3.7)$$

The Reynolds number is calculated using

$$Re = Ux/\mu \quad \text{per meter} \quad (3.8)$$

The local Reynolds number, Re_x , is found by multiplying Re by the x location from the leading edge of the plate.

$$Re_x = Ux^2/\mu \quad (3.9)$$

3.4.2 Oblique Shock Theory

From the calibration tests, it is assumed throughout the study that the uniform free jet has a Mach number of 6.0. When the model is at 0° incidence, the flat plate will theoretically see a flow of Mach 6.0. Almost all of the tests completed in this study were with the plate at zero degree incidence. Some preliminary tests were completed at a different Mach number. Since the H-3 tunnel has a fixed geometry nozzle, the only way to change the Mach number of the flow over the plate is to put the plate at a negative angle of attack (leading edge down). Theoretically, when the plate is at a negative angle of attack, a weak oblique shock is formed and the Mach number downstream of the shock will need to be calculated using oblique shock theory. In reality, due to the presence of the boundary layer, an extremely weak oblique shock is formed when the plate is also at zero degree incidence.

Figure 3.3 gives the orientation of the plate and defines the incidence angle of the plate, α , and the shock angle, θ . The Mach number behind the shock can be calculated using the following equation (17:492).

$$M_2^2 = \frac{1 + .5(\gamma-1)M_1^2}{\gamma M_1^2 \sin^2 \theta - .5(\gamma-1)} + \frac{M_1^2 \cos^2 \theta}{1 + .5(\gamma-1)M_1^2 \sin^2 \theta} \quad (3.10)$$

3.4.3 Heat Transfer

The heat transfer distribution on a flat plate, Figure 2.6, distinguishes three regions; laminar, transition, and turbulent. For the case of an isothermal flat plate in the absence of leading edge and viscous interactions, i.e., conditions at the edge of the boundary layer are those of the free stream, Korkegi (31:124) gives approximate expressions for laminar and turbulent Stanton numbers for compressible flows. These equations are obtained from approximate expressions for laminar and turbulent skin friction based on a "reference" temperature T_f .

For laminar flow:

$$St = \frac{0.41}{Rex^{1/2} (T_f/T_\infty)^{.12}} \quad (3.12)$$

$$T_f/T_\infty = 1 + .032 M_\infty^2 + .58 \left[\left(\frac{T_w}{T_\infty} \right) - 1 \right] \quad (3.13)$$

For turbulent flow:

$$St = \frac{0.037}{Rex^{1/5} (T_f/T_\infty)^{.648}} \quad (3.14)$$

$$T_f/T_\infty = 1 + .035 M_\infty^2 + .45 \left[\left(\frac{T_w}{T_\infty} \right) - 1 \right] \quad (3.15)$$

where T_∞ is the freestream static temperature and Rex is defined by eqn (3.9). The experimental data will be plotted with these approximate expressions for comparison purposes.

3.5 Description of Test Models

The dimensions of the flat plate were chosen to be 150 mm in length and 100 mm in width. The rear edges of the

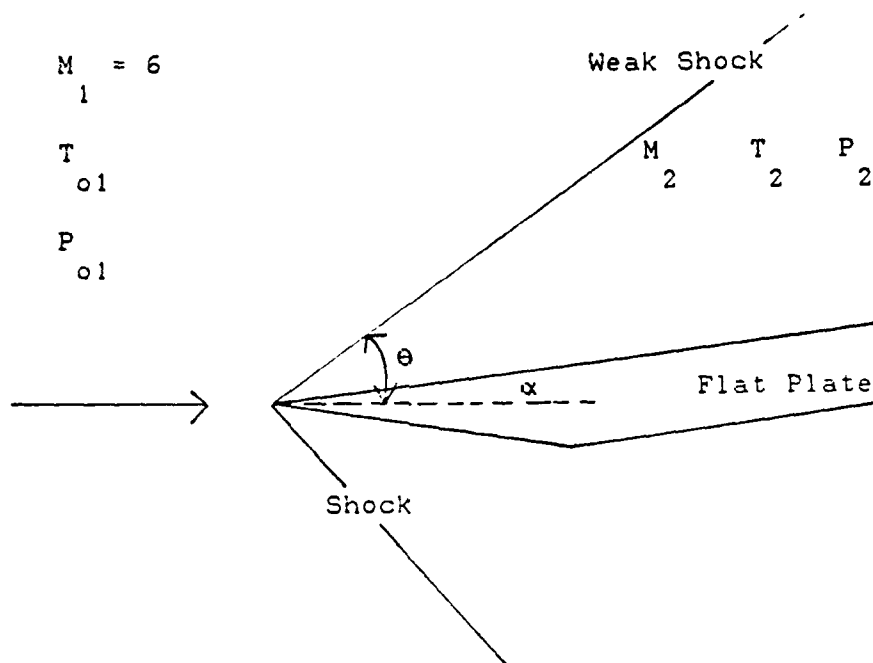

Figure 3.3. Oblique Shock Configuration

The NACA tables (2:22,42,43) have oblique shock data, so if α and M_1 are known, θ can be obtained. Then, the normal component of the Mach number, $M_1 \sin \theta$, can be calculated and the ratios P_2/P_1 , and T_2/T_1 can be obtained from normal shock tables. For this study,

$$\alpha = -5.5^\circ$$

$$\theta = 13.5^\circ$$

$$P_2/P_1 = 2.12$$

$$T_2/T_1 = 1.255$$

(3.11)

Therefore, $M_2 = 5.26$.

plate will therefore be slightly in the shear layer, but no data will be taken near those regions.

The oil flow and sublimation visualization tests for the flat plate were completed on a plexiglas model and repeated with an aluminum model. The dimensions of the model are shown in Figure 3.4. The top surface of the model for the oil and sublimation experiment was sprayed with a dark blue color. The tests done with the plexiglas model were repeated since the leading edge was easily damaged during the tests by particles in the flow. Small nicks in the leading edge caused large disturbances in the oil flow tests. The plexiglas model was chosen initially for the test since it was already machined and had the correct dimensions.

The liquid crystal test was completed on a stainless steel model with a plexiglas insert. The dimensions of the model are shown in Figure 3.5. A single coax gage was installed in the stainless steel portion of the model for calibration purposes. The model was painted black and then the liquid crystals were sprayed on the entire model.

The heat transfer test for a flat plate was completed on a stainless steel model. The dimensions of the model are shown in Figure 3.6. The model had two coax gages installed in it and also had a ceramic insert for the thin film gages.

The aluminum flat plate, with its previously described dimensions shown in Figure 3.4, was used in the three

dimensional flow visualization tests. Five fins of varying sweep angle and height, were constructed out of bronze and sequentially placed on the model for the sublimation and oil flow tests. The dimensions of the fins are shown in Figure 3.7.

It was desired to determine the location of transition on the undisturbed flat plate so that a laminar interaction with the fin could be studied. Experimental data from previous VXI studies completed in the H-3 wind tunnel were examined. Table 3.1 shows the results that were found.

Table 3.1. Location of Transition

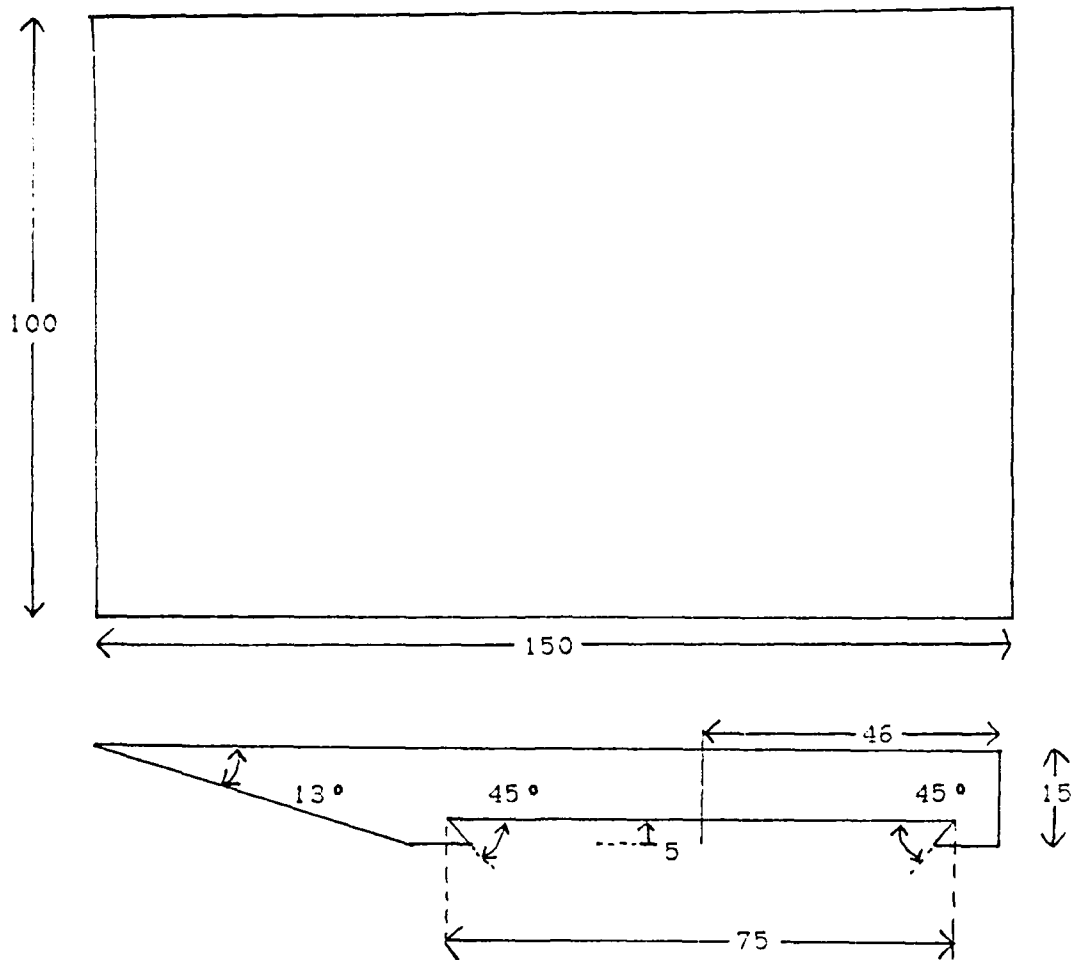

Mach Number	Re (/m)* -7 x10	x transition (mm)	Reference
5.2	3.2	110	(14)
5.2	1.6	120	(14)
6.0	2.3	95	(15)
6.0	1.7] test conditions of this study	
6.0	0.84		

* based on Keyes viscosity law

Table 3.1 shows that as the Reynolds number is decreased, the transition location moves downstream. Therefore, transition is expected to occur at least 95 mm downstream of the plate leading edge for the test conditions in this study. A more accurate determination of the transition

location was determined in later tests. The results are discussed in section 3.7.4. Therefore, to obtain a laminar interaction, the fins were installed so that the leading edge of the fin was approximately 60 mm downstream of the leading edge and 40 mm from the right side of the plate when looking forward from the rear of the plate.

The heights of the fins were chosen so there would be no interference with the oblique shock originating at the plate leading edge when the plate was at -5.5° angle of attack (Mach 5.26). This height was calculated using the theoretical shock angle and then verified for "no interference" using the shadowgraph technique. However, once the sublimation tests began and the phenomena of interest was detected for the Mach 6 test case, the Mach 5.26 test case was dropped from the remainder of the test plan. Since the fins were already machined at the shortened height and had already been used for the oil flow tests they were retained for the remainder of the test plan. Future tests at Mach 6 should be completed with taller fins to determine if fin height produces any difference in the flow field for varying values of fin sweep and incidence angle.

3.6 Experimental Techniques

3.6.1 Oil Flow Visualization Technique

The surface oil flow technique is intended to quickly and easily investigate the nature of the flow over the surface of a wind tunnel model. A mixture of gasoline, titanium (IV) oxide (talcum powder), and oleic acid was used for the flat plate tests, but was found to be inadequate for the three dimensional flow visualization. A new mixture of motor oil and titanium oxide was used with excellent results. The surface of the model was lightly painted with the oil mixture. The air flowing over the surface carries the oil with it and leaves a streaky deposit of the powder remaining to mark the direction of flow. The patterns made by the streaks indicate the surface streamlines and the local direction of flow on the surface.

In interpreting oil flow patterns, Maskell's definition of a three dimensional separation line is used (40:161). This says that

"the three dimensional separation line is an envelope of converging limiting surface streamlines."

In many three dimensional situations, oil may accumulate along a line because the surface shear becomes too low to overcome the friction and surface tension of the oil. Care must be taken not to interpret this accumulation line as a separation line. The true separation line, in the Maskell sense, has streamlines converging on it from either side.

Another complication in interpreting oil flow patterns in three dimensional flow interactions is the separation line in the absence of an oil film and the line of oil accumulation will differ due to two reasons (51:29):

1. The effective body shape of the model will be altered by the change of the oil film height, thus altering the inviscid flow properties.
2. The separation of the air flow will be delayed in the presence of an oil film, due to the finite velocity of the air at the oil surface. This will increase the momentum of the air boundary layer leading to flow separation at a place of higher pressure gradient.

This difference is illustrated in Figure 3.8. However, since these influences are small, the oil flow technique is still a very valuable visualization tool.

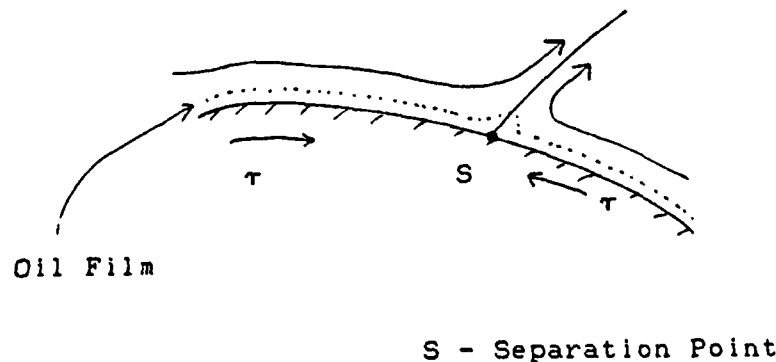

Figure 3.8. Separation in Oil Flow Experiments

The ratio of ingredients, oil : powder, to achieve good test results is a matter of trial and error. For these tests, a thin consistency mixture produced the best results. However, if the mixture was too thin, the oil tended to drip too fast over the plate after the plate is taken out of the injected position, therefore ruining the important patterns. Painting the model with a minimum quantity of the mixture, also seemed to work best.

3.6.2 Sublimation Visualization Technique

The sublimation method is a visualization technique to detect the location of the transition and turbulent regions (51:19-21). The technique consists of coating the model surface with a dark colored paint, and then coating the model with a thin, constant thickness layer of a subliming material, in this case, acenaphthene. The acenaphthene is dissolved in ether and sprayed on the model. The ether evaporates quickly and leaves the white acenaphthene on the model. During exposure to an airstream, sublimation occurs along the surface at varying rates, depending on the diffusion mass transfer of the substance in gaseous form into the air boundary layer. The diffusion mass transfer rates depend on the character of the boundary layer; whether it is laminar, transitional, or turbulent. The mass transfer of an attached turbulent boundary layer is approximately one order of magnitude larger than for an attached laminar boundary layer (51:19).

For zero pressure gradient boundary layers, Reynold's analogy states that the amount of heat transfer (characterized by the Stanton number), can be directly related to the momentum transfer (skin friction coefficient). The heat transfer can also be related to the mass transfer. This relation is explained in detail by Stock (51:22-23). The skin friction coefficient, c_f , distribution in a flat plate boundary layer is shown in Figure 3.9. From Figure 3.9, it can be seen that the regions of highest skin friction coefficient will sublime first - exposing the dark model underneath. Therefore, an indication of the location of transition will be determined using the sublimation technique.

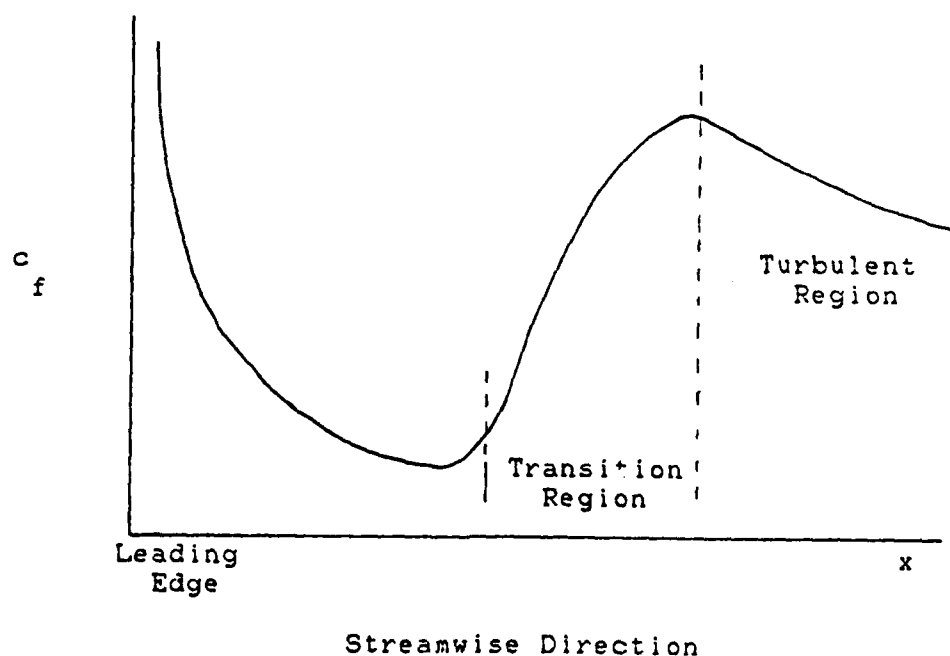

Figure 3.9. Skin Friction versus Streamwise Direction

For three dimensional flows, regions near the fin on the flat plate will also have different skin friction coefficients so the sublimation technique will also be used to examine this flow interaction region.

3.6.3 Shadowgraph Optical Technique

A popular optical system used in wind tunnels is the shadowgraph system. The principal behind the shadowgraph technique is very similar to the schlieren technique, except that there is no knife edge. The shadowgraph system gives an image representative of the variation of density gradients throughout the complete flow field. The VKI H-3 wind tunnel has a "double-pass" shadowgraph/schlieren system, that is, the light rays are passed through the test section twice. When axisymmetric models are being tested, the double-pass system is used rather than a single-pass system because in hypersonic tunnels the test section density is very low. Therefore it is usually difficult to obtain high quality shadowgraph or schlieren pictures with a single-pass system (42:233).

The shadowgraph photographs were used to examine the height of the laminar boundary layer, the shock formed from the leading edge of the flat plate at incidence, and the flow interaction with the fin.

3.6.4 Liquid Crystal Technique

The liquid crystal technique is a qualitative and semi-quantitative technique to visualize the global heating of an

area of interest. An advantage of using liquid crystals over phase change paints is that a coat of liquid crystals can be used for several tests. Phase change materials must be reapplied for every test, which is very inconvenient. Liquid crystals also have a response time on the order of milliseconds (47:15) making it more effective for transient heat transfer tests.

The liquid crystals that will be used in this test are cholesterics. Cholesteric molecules have a helical structure. One of the most interesting properties of the cholesterics is the influence of the temperature on their structure. When a light beam is sent parallel to the helical axis, the reflected wave length depends on the characteristics of the lattice and also on the angle of observation. Therefore, when the helical structure changes with temperature, the reflected wavelength will also be modified, and if the wavelength is in the visible spectrum, the temperature will be associated with a change of colors. The typical colors that will be encountered in this test are red (24.5°C), yellow, green, and blue (28.5°C).

The helical structure of normal liquid crystals are sensitive to shear stress. The shear stresses produced by hypersonic flows produce shifting of the helical structure, thus changing the reflected wavelength. It is impossible to determine in a wind tunnel whether a change of color is due to temperature or shear stress. To overcome this problem,

C encapsulated liquid crystals are used. Small droplets of the cholesteric material are embedded in gelatin bubbles with a diameter of three to five micron. This gelatin bubble shields the liquid crystals from shear. Disadvantage of the encapsulation will be loss in the brilliancy of the colors.

(To determine the temperature changes of a surface due to a flow, the surface material should have a low thermal conductivity. Since it is desired to record the changes seen by the liquid crystals, it is important that the heat does not conduct through the material. If this should occur, then the heat transfer effects seen will be much lower than in reality due to the conduction effects. The tests will therefore be completed on a plexiglas insert rather than directly on the metal model.

C The surface color changes for the flat plate tests will be recorded by color photographs during each test. With an accurate correlation between color and temperature, the temperature time history can be determined. For complicated flows, the color changes could be recorded by a color video camera and the determination of the temperature could be enhanced with the use of a digital image processing (DIP) technique which can distinguish between shades of red, green, or blue from the intensity. For completeness, the DIP is explained in a little more detail in Appendix G.

3.6.4.1 Theory

Once the surface temperatures are determined from the liquid crystals, the heat transfer rate can be determined. To obtain the relation to solve for the heat transfer rate from surface temperature, the one dimensional heat equation must be solved for an initially isothermal semi-infinite slab. The heat equation is

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial y^2} \quad (3.16)$$

The solution of the heat equation is shown in great detail by Degrez (15:57-60). If $T_s(0)=0$, and if the heat flux is a constant in time,

$$q = \frac{(\rho c p k \pi / t)^{1/2}}{2} T_s(t) \quad (3.17)$$

The Stanton number can then be calculated using

$$St = \frac{HC}{c p \phi - U_\infty} \quad (3.18)$$

where HC is the heat transfer coefficient and is defined by

$$HC = \frac{q}{T_{AW} - T_W} \quad (3.19)$$

T_{AW} is the adiabatic wall temperature and is defined by

$$T_{AW} = T_\infty [1 + .5r(\gamma - 1)M^2] \quad (3.20)$$

where r is the recovery factor, and for laminar flow is

$$r = Pr^{1/2} \quad (3.21)$$

3.6.4.2 Validity of Assumptions

The assumptions used in the theoretical analysis of the liquid crystal technique are

- 1) one dimensional heat transfer
- 2) semi-infinite slab
- 3) constant heat flux
- 4) liquid crystals do not disturb the surface heat flux to the model

Each assumption will be examined to determine if it is valid for the conditions of the test.

The heat transfer into the model must be one dimensional. This will be assumed to be true for the model, except near the edges of the model or at any discontinuity of the material.

The plexiglas on which the liquid crystals are mounted must be thick enough so that the heat transfer into the substrate is similar to that of a semi-infinite solid. Therefore, the base of the plexiglas should remain at a constant temperature. The thickness at which T_x/T_s and q_x/q_s remain smaller than 1% for a given time is approximately (48:8)

$$x = 4 (\alpha t)^{1/2} \quad (3.22)$$

This equation can then be solved for t . Since the thickness of the plexiglas is five mm, the time at which the semi-infinite slab assumption is valid is shown in Table 3.2 for plexiglas, and also stainless steel and aluminum for

comparison. Table 3.2 clearly shows why the plexiglas insert was chosen for the test.

The third assumption used in the analysis was constant heat flux. The validity of this assumption can be examined at the conclusion of the test. When the heat transfer rate is constant, the surface temperature increases as the square root of t . This can be seen from equation (3.17). If $(T_s)^2$ versus t is plotted, the resulting curve should be a straight line. If the line is not straight, the constant heat flux assumption is not valid.

Table 3.2. Semi-infinite Slab Criteria

	Plexiglas	Stainless Steel	Aluminum
$\rho(\text{kg/m}^3)$	1.19×10^3	7.9×10^3	2.7×10^3
$k(\text{Watts/m}^\circ\text{K})$	0.188	15.0	
$cp(\text{J/kg}^\circ\text{K})$	1463	440	
$\alpha(\text{cm}^2/\text{sec})$	0.0011	0.043	0.85
$t(\text{sec})(x=5\text{mm})$	14.5	0.36	0.018

The fourth assumption used in this technique is that the liquid crystals do not disturb the surface heat flux to the model. This will be assumed to be true since the layer of liquid crystals is very thin, on the order of 10^{-6} meter.

3.6.4.3 Calibration of the Liquid Crystals

The calibration of the liquid crystals is critical in that it is the basis of the correlation between the colors on the photograph and temperature on the surface of the model. The calibration is performed on the metal portion of the model. A coax gage is installed in the stainless steel and the entire model is sprayed with the liquid crystal solution. The details of the model preparation are described in Appendix F. Details concerning the coax gage will be considered in section 3.6.6. Since metals are good heat conductors, the temperature found by the coax gage can be assumed to be uniform. This will also be shown during the calibration if the liquid crystals on the metal portion are a uniform color.

To obtain calibration data that will be applicable to the subsequent tests, the same conditions must be present for the calibration as the actual tests. This requires that the position of the model, camera, and light remain constant. The position of the model for filming will always be in the injected "test" position. The camera and light should not be moved after the calibration until all the tests are completed.

After the model is installed in the tunnel, a vacuum pump is installed to produce a vacuum in the test chamber. The purpose of the vacuum is to prevent any convective heating. Since it is impossible to seal the H-3 chamber,

the vacuum pump evacuates the test chamber to approximately 0.4 bar, this taking about two hours. The amount of convective heating should be very small at this low pressure. The model is placed in the injected position where it is heated by two 1000 watt lamps until the model has reached at least the temperature that corresponds the color of the liquid crystals. The highest temperature visualized by the liquid crystal corresponds to the blue color. The plate required over 60 seconds of heating before the first color appeared. Then the lights are turned off and the model is allowed to cool. When the liquid crystals on the metal portion of the model reaches a uniform color, or steady state temperature, the model is photographed and the voltage from the coax gage is recorded. The model is then allowed to cool some more and this process is repeated until all the colors have been photographed.

3.6.5 Thin Film Heat Transfer Gages

The thin film technique is well suited for measurements in transient conditions due to the fast response time. However, thin film gages have a disadvantage that large errors can occur if used for long duration tests, due to nonisothermal wall effects. The thin film gage is actually a thin-film surface resistance thermometer. The gages consist of thin metallic films applied to the surface of substrates of low heat conductivity. If the thin film gages are properly made, the heat flow into the substrate is one

dimensional and similar to that of heat flow into a semi-infinite solid. The variation of temperature with time is obtained from the thin film gages. The gages become one leg of a wheatstone bridge. Before a test, at ambient conditions, the bridge is balanced. During a test, as the plate is heated the resistances of each gage change and the unbalance of the bridge can then be related to the variation of temperature. The heat flux may then be deduced using a numerical procedure or an electrical analog circuit.

The construction of a thin film gage requires a lot of time, patience, and very precise workmanship. The instructions will not be elaborated upon in this report but the details of the construction of a thin film gage are explained very well by Ligrani, et al (37:3-10). Since ceramic is easier than quartz to machine to precise dimensions, ceramic was chosen as the substrate for the thin film gages in this study. The dimensions of the ceramic must be chosen carefully because the depth of the substrate is dependent on the tunnel running time. Since the semi-infinite slab assumption is used in the data reduction technique, this aspect must be considered.

3.6.5.1 Theory

The one-dimensional heat equation, equation (3.16) is used in the analysis of thin film gage data. Recall that the detailed solution of the one-dimensional heat equation is given in (15:57-60). However, at this point in the

analysis, the heat flux is not yet assumed to be constant. The equation for the heat flux is given by:

$$q_s(t) = \frac{(\rho c p k / \pi)^{1/2}}{2} \left[\frac{2T_s(t)}{t^{1/2}} + \int_0^t \frac{T_s(t) - T_s(\tau)}{(t-\tau)^{3/2}} d\tau \right] \quad (3.23)$$

The evaluation of the heat transfer rate from the observed surface temperature record may be obtained by integrating eqn (3.23) numerically or by the use of electrical analogs.

Arts (5) mentions that the method using the electrical analog circuit to integrate the temperatures is more accurate than the numerical integration methods due to the uncertainty of the exact time of the beginning of the heat flux. If the exact time of the beginning of the heat trace is not known, an approximate time is used for the numerical integration methods. This error is then propagated in the numerical integration. The electrical analog circuit method, is not as sensitive to this problem.

For either method, the surface temperature rise, $T_s(t)$, in equation (3.23) is found from the resistance change of the thin film. For the film,

$$R = \frac{R_{REF} [1 + \alpha (T - T_{REF})]}{R} \quad (3.24)$$

where R is the film resistance at surface temperature T , R_{REF} is the film resistance at temperature T_{REF} , and α is the film temperature coefficient of resistance. By Ohm's law, when the film is supplied with a constant current

$$V = V_{REF} \left[1 + \frac{\alpha}{R} (T - T_{REF}) \right] \quad (3.25)$$

If the reference voltage V_{REF} is measured at the ambient temperature, T_a , before a test then $T_a = T_{REF}$, and

$$T_s = \frac{\Delta V}{\frac{\alpha}{R} V_{REF}} \quad (3.26)$$

where ΔV is the film output voltage, $V - V_{REF}$, and V_{REF} is the initial film voltage.

The numerical computation of heat transfer rate from the temperature measurements can be made on the basis of equation (3.23). This method may be called a direct method in that $q(t)$ is obtained directly. Note that there is a singularity at $t = \tau$. If $\Delta V(t)$ is assumed to be piecewise linear the final equation is

$$q_s(t_n) = \frac{2(\rho c_p k / \pi)}{\frac{\alpha}{R} V_{REF}} \sum_{i=1}^{1/2 n} \frac{\Delta V(t_i) - \Delta V(t_{i-1})}{\frac{1}{2}(t_n - t_{i-1}) + \frac{1}{2}(t_n - t_i)} \quad (3.27)$$

where $\Delta V(t)/(\frac{\alpha}{R} V_{REF})$ is the rise in surface temperature $T_s(t)$ as shown in equation (3.26). To use eqn (3.27), it is generally necessary to eliminate any noise from the data before integration. Details of the derivation of equation (3.27) can be found in Schultz and Jones (48:35-37).

Another method to numerically compute the heat transfer rate from temperature measurements is an indirect method, in that $Q(t)$, the cumulative heating, is obtained first and then differentiated with respect to time to obtain $q(t)$.

$$Q_n(t) = \frac{(\rho c p k / \pi)}{\alpha V_{REF} R} \sum_{i=0}^{1/2 n} \frac{[\Delta V(t_i) + \Delta V(t_{i+1})] \Delta t}{(t_n - t_i)^{1/2} + (t_n - t_{i+1})^{1/2}} \quad (3.28)$$

$$q(t) = \frac{dQ(t)}{dt} \quad (3.29)$$

This differentiation is performed using a 4 point central finite differencing scheme

$$q(t) = \frac{-2Q(i-8) - Q(i-4) + Q(i+4) + 2Q(i+8)}{40 \Delta t} \quad (3.30)$$

In the indirect method, the integration tends to smooth the data and no preliminary noise reduction is necessary. The only approximation used in equations (3.27) and (3.28) was the local linearization of $\Delta V(t)$.

If the electrical analog circuit is used to do the integration in equation (3.23), an examination of the analog circuit is warranted. The electrical analog circuits are explained in detail in Appendix H. From the solution of the one dimensional heat equation, assuming that the heat flux is constant, equation (3.31) gives the heat flux in terms of surface temperature.

$$q_s(t) = \frac{1}{2} (\rho c p k \pi / t)^{1/2} T_s(t) \quad (3.31)$$

If equation (3.26) for T_s is substituted into equation (3.31), then

$$q_s(t) = \frac{1}{2} (\rho c p k \pi / t)^{1/2} \frac{\Delta V}{\alpha V_{REF} R} \quad (3.32)$$

where α_R is determined for each gage before testing using the equation

$$\alpha_R = \frac{1}{RREF} \frac{(R - RREF)}{(T - TREF)} \quad (3.33)$$

If this calibration is done on a different day than the test itself, the ambient temperature may be different. Therefore, the measurement of RREF may be made at a temperature TREF different than the gage temperatures initially before a test, Ta. In order to correct for this difference, the value of α_R in eqn (3.33) must be corrected before data reduction. Correcting for this effect, equation (3.32) becomes

$$q_s = \frac{(\rho c p k \pi / t)}{2} \frac{\Delta V}{\alpha_R VREF} [1 + \alpha_R (Ta - TREF)]^{1/2} \quad (3.34)$$

which is then the same as equation (3.32) when Ta = TREF. Typically, this correction term may account for 1% of q_s if the difference of the temperatures is between 5 to 10°C.

From the electrical analog circuit analysis in Appendix H, where VOUT is the voltage output from the analog circuit,

$$\frac{\Delta x}{\beta} = \frac{\Delta V}{2 VOUT} (\pi / t)^{1/2} \quad (3.35)$$

solving for ΔV and substituting into equation (3.34) the new equation for the heat flux is

$$q_s = \frac{VOUT}{VREF} \frac{(\rho c p k)}{\alpha_R} \frac{\Delta x}{\beta} [1 + \alpha_R (Ta - TREF)]^{1/2} \quad (3.36)$$

The calibration of the thin film gages and determination of all the terms in equation (3.36), V_{REF} , α , $(\rho c p k)^{1/2}$, and $A \times / \beta$, are described in detail in Appendix I.

3.6.5.2 Validity of Assumptions

The assumptions used in the theoretical analysis of the thin film gage technique are

- 1) one dimensional heat transfer
- 2) semi-infinite slab
- 3) thin film gages do not disturb the surface heat flux to the model

and for the electrical analog integration, an additional assumption is

- 4) constant heat flux

Each assumption will be examined individually to determine its validity.

The heat transfer into the model has been assumed to be one dimensional. This will be valid provided the gages are not placed near the edges of the substrate or near the holes in the substrate which may be used for wire connections. A rule of thumb is to place gages away from substrate discontinuities at distances equivalent to or greater than those required for a semi-infinite substrate behavior.

The ceramic on which the gages are mounted must be thick enough so that the heat transfer into the ceramic is similar to that of a semi-infinite solid. It is desired

that the base of the ceramic should remain at a constant temperature. The thickness at which T_x/T_s and q_x/q_s remain smaller than 1% for a given time has been previously given in equation (3.22). For a substrate thickness of 2.5 mm, the test time for a valid test has been determined to be approximately 0.65 seconds.

The third assumption used in this technique is that the thin film gage does not disturb the surface heat flux to the model. This will be assumed to be true since the layer of metal film is very thin, on the order of 10^{-6} to 10^{-7} m (37:23) and it has a high thermal conductivity.

For the electrical analog circuit, the theoretical analysis had an additional assumption: constant heat flux. Again, the validity of the assumption will be considered later by plotting T_s^2 versus t and examining its deviation from a straight line.

3.6.5.3 Data Acquisition - Numerical

Data acquisition for the numerical technique will consist of determining $\Delta V/(\alpha V_{REF})$. α will have been determined previously as explained in Appendix I. However, before a test can even be started, the data channels of the acquisition system must be calibrated. Using the variable resistors in the current generator box, the Wheatstone bridge must be balanced before any calibration or test. The output from the bridge should pass through the amplifier and be recorded by the data acquisition system. These data

units should be close to zero for a balanced bridge. A resistor, R_a , is then added in series to the thin film gage. The output of the data acquisition system can then be amplified to cause the output to be near the full scale of the data acquisition system. The calibration coefficient may then be expressed in terms of ohms/digital units. Once the calibration coefficient is established, the amplifier setting for each data channel must not be changed. The resistance, R_a , is chosen using the resistance versus temperature calibration plots for α for each gage depending on the expected maximum temperature rise R during an actual test.

During a test, the thin film gages are supplied with a constant current by a differential amplifier circuit. The voltage output of the gage may be read from the readout window on the current generator. At ambient conditions before a test, the voltage read from this window is V_{REF} , the initial film voltage. The resistance of the thin film gage, R_{FILM} , should also be recorded by an ohm meter at ambient conditions before test, to determine the initial temperature of the gage.

The voltages are then numerically integrated using equation (3.27) or (3.28). The program used to perform this integration is shown in Appendix L. Once the heat transfer rate is determined, the Stanton number can be calculated using equations (3.18) through (3.21).

3.6.5.4 Data Acquisition - Electrical Analog

The voltage output of the gage is determined exactly as previously described in the data acquisition for the numerical technique. However, the calibration of the data channel as described using a resistor in series with the gages is not necessary since the electrical analog circuit will be used to reduce the data from the thin film gages. The data channels will be calibrated in conjunction with the analog circuit, as described in Appendix I when determining the A^*/β term.

The output from the thin film gage after amplification is connected to the analog circuit which allows the conversion of a parabolic wave into a step wave. The output from the analog circuit is then amplified again, and the output is called VOUT. Using equation (3.36), the heat transfer trace can be obtained. This trace should be examined, and a time interval, from τ_1 to τ_2 , over which steady flow conditions are present should be chosen. The time interval is important for signal processing. It should be long enough to obtain enough data points for a least squares data fit, but also should not include intervals when flow conditions are not well established, i.e., during model injection. This time interval chosen will correspond to temperatures T_1 and T_2 .

The next step in the signal processing is to reconstruct the surface temperature versus time trace from a

given heat transfer rate versus time trace. This is done using an equation given by Oldfield, Jones, and Schultz (37:34)

$$\Delta T_s(t) = \frac{4}{3} (\rho c p k \pi)^{-1/2} \sum_{n=0}^m \left[q_{n+1} + q_{n-1} - 2q_n \right] (t - t_n)^{3/2} H(t - t_n) \quad (3.37)$$

In equation (3.37), q_n is the measured heat transfer rate at time $t_n = n\Delta t$. $H(t - t_n)$ equals 1 for $t \geq t_n$, and zero for $t < t_n$. If the time t may be expressed as $m\Delta\tau$, where $\Delta\tau$ is the time interval between data samples, then equation (3.37) may be rewritten as:

$$\Delta T_s(m\Delta\tau) = \frac{4}{3} [\Delta\tau / (\pi \rho c p k)]^{1/2} \sum_{n=0}^m \left[q_{n+1} + q_{n-1} - 2q_n \right] (m - n)^{3/2} \quad (3.38)$$

Alternatively, if q_{n+1} , q_{n-1} and q_n are expressed in terms of data units instead of dimensionally in watts/m²,

$$\Delta T_s(m\Delta\tau) = D \sum_{n=0}^m \left[Nq_{n+1} + Nq_{n-1} - 2Nq_n \right] (m - n)^{3/2} \quad (3.39)$$

where

$$D = \frac{4}{3} [\Delta\tau / (\pi \alpha V_{REF})]^{1/2} \frac{A^*}{\beta} \quad (3.40)$$

Equations (3.37) through (3.40) are based on a fit of the heat transfer versus time trace using a series of ramps. The derivation of equation (3.37) is given in (37:44). The

computer program used for the reconstruction of the temperature versus time trace is shown in Appendix M.

After obtaining the heat flux versus time and the temperature versus time plots, the heat transfer versus temperature curve may be constructed. A least squares data fit to a straight line is made between the two temperatures, T_1 and T_2 . This line is then extrapolated back to the value of q_s at the initial test surface temperature which is usually the same as ambient. This value of q_s is then equivalent to that obtained for isothermal test conditions. The program used to find the isothermal heat flux is listed in Appendix N. Once the heat transfer rate is determined, the Stanton number can be calculated using equations (3.18) through (3.21).

3.6.6 Co-axial Thermocouple Gages

The coax heat transfer gage is a coaxial surface thermocouple. The temperature time history is obtained from this gage and used to determine the surface heat flux. The coax gage assembly is illustrated in Figure 3.10. An electrically insulated center conductor, chromel, is enclosed within a cylindrical jacket of constantan. The surface thermocouple junction is formed by the vacuum deposition of a metal about one micron thick. An advantage to the use of the coax gage is that it is thermally matched

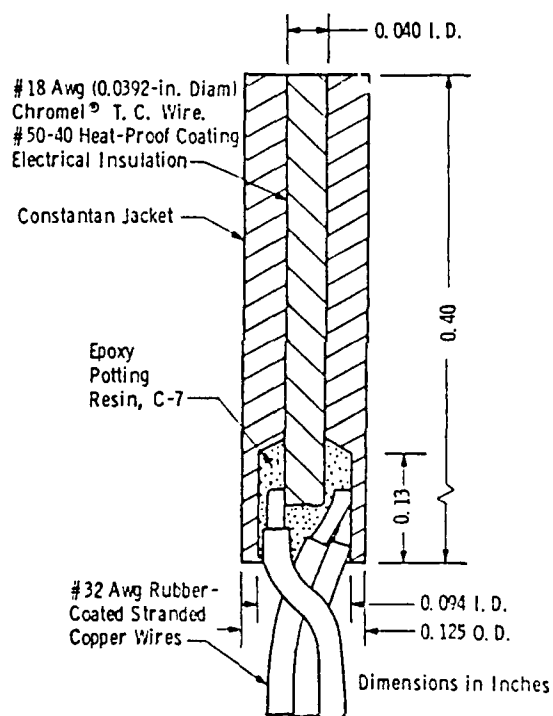

Figure 3.10. Coax Gage Assembly

to the model, therefore allowing it to be used for long duration tests. A disadvantage with the coax gages is that it has a low output.

The choice of material for the center conductor and outer cylindrical jacket is dependent upon the test model material, or vice versa. In this test, the material is stainless steel, so the thermal properties of the gage must be similar to that of stainless steel. Chromel and constantan fulfill this requirement, as shown in Table 3.3 (10:7). The stainless steel used for the model was AISI 304 stainless steel.

Table 3.3. Thermal Properties of Materials

	$\frac{1}{2}$ ($\rho c p k$)	α	cp	k
	$\frac{1}{2}$ $\frac{\text{BTU/sec}}{\text{ft}^2 \text{ } ^\circ\text{F}}$	$\frac{\text{ft}^2}{\text{hr}}$	$\frac{\text{BTU}}{\text{lb } ^\circ\text{F}}$	$\frac{\text{BTU}}{\text{ft hr } ^\circ\text{F}}$
Chromel	0.410	0.19	0.107	11.0
Constantan	0.408	0.23	0.098	13.0
304 Stainless Steel	0.353	0.17	0.105	8.7
17-4 PH Stainless Steel	0.409			
302 Stainless Steel		0.16	0.110	9.4
410 Stainless Steel		0.27	0.110	14.0
Aluminum		3.30	0.214	119.0
Copper		4.30	0.092	219.0

The coax gage is installed through the model wall so that the outer model surface temperature may be measured using wires emerging from the back surface. The gages used in this study have an additional wire that enables the measurement of the temperature of the back side of the gage. This is significant in that these coax gages are not restricted by the semi-infinite slab assumption used by many other heat transfer gages. During long tests, the back side temperature rise can be monitored and accounted for in the data reduction technique.

The popularity of the coax gage has arisen due to several reasons (10:6). The coax gage measures surface temperatures more accurately than other gages because the conduction losses are minimized since the thermocouple materials are actually part of the wall, ie, have the same thermal properties as the wall material. The gage is durable in that it is able to withstand high levels of erosion during testing. The gage may be contoured exactly to the model surface by sanding, so convective or other material flow over the surface is undisturbed. Also the small mass of the thermal junction allows a nominal response time of approximately one microsecond for the vacuum deposited junction or ten microseconds for junctions created by sanding. The coax gage can also be manufactured very small, which allows a very close spacing of thermocouples. The gages are available in probe diameters starting from

0.015 inches (0.381 mm). Also, the voltage versus temperature correlation is a property of the gage materials and is already determined by the manufacturer so no gage calibration is necessary.

3.6.6.1 Theory

The heat equation for one dimensional flow is:

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial y^2} \quad (3.41)$$

To account for gage back side heat loss, a finite difference solution of the heat equation was developed (25:3). A simple forward time and central spaced explicit method was applied to the heat equation.

$$\frac{T(N+1,I) - T(N,I)}{\Delta t} = \alpha \frac{T(N,I+1) - 2T(N,I) + T(N,I-1)}{(\Delta y)^2} \quad (3.42)$$

Solving for $T(N+1,I)$ results in the following equation.

$$T(N+1,I) = \Theta_s [T(N,I-1) + T(N,I+1) + (1/\Theta_s - 2) T(N,I)] \quad (3.43)$$

The heat transfer rate is solved using a three point forward differencing scheme.

$$q(N) = -\frac{k}{2\Delta y} [-3T(N,wall) + 4T(N,wall+1) - T(N,wall+2)] \quad (3.44)$$

$$\text{where } \Theta_s = \frac{\alpha \Delta t}{\Delta y^2} \quad (3.45)$$

For this scheme, boundary conditions are imposed to force the temperature at the inner wall surface ($I=1$) to match the coax gage surface temperature while the gage back side temperature ($I=I_{max}$) is forced to match the back side

temperature measurement. An important restriction for the NSWC method is that the stability constant, Θ_s , must be less than 0.5 for the solution procedure to be numerically stable.

3.6.6.2 Validity of Assumptions

For the coax gage, there are only two assumptions used in the analysis and technique,

- 1) one dimensional heat transfer
- 2) coax gage does not disturb the surface heat flux to the model

Each assumption will be considered individually for its validity.

One dimensional heat transfer is assumed to be true since the thermal properties of the gage are similar to those of the stainless steel model. In complicated flows with high heating in localized areas, insulation of the gage may be required so that the peak heating from one point does not conduct laterally to a neighboring gage. For short coax gages, a portion of the heat transfer in the lateral direction can be taken into account by the use of the back face gage. However, for this study, the test duration is very short - approximately 500 milliseconds, so one dimensional heat transfer is assumed to be correct.

It is also assumed that the gage does not disturb the surface heat flux to the model since the gage is installed

in the body of the model. The surface of the gage is installed flush with the model surface.

3.6.6.3 Data Acquisition

The data acquisition involves recording the voltage from the coax gage. However, before the data channel of the acquisition system is used to process the signal from the coax gage, calibration of the amplifier and data channel is required. The calibration is completed by placing a known dc voltage into the amplifier and recording the data units from the data acquisition system to determine a volts/unit calibration constant.

Once the voltage from the coax gage is known, the temperature of the surface and back side can be determined using the calibration tables supplied by the manufacturer. These tables, referenced at 0°C, are included in Appendix Q. Once the surface and back side temperatures are known, the heat transfer rate can be determined using equations (3.43) through (3.45). Appendix R lists the computer program used for this computation. Once the heat transfer rate is known, the Stanton number can also be determined using equations (3.18) through (3.21).

3.7 Results of the Flat Plate Study

Table 3.4 shows the test conditions for all the photographs included in this report for tests on the flat plate. Appendix S shows the test conditions and VKI photograph catalog numbers for every test completed in this study. The shadowgraph photographs showed the undisturbed boundary layer height at approximately 60 mm from the plate leading edge to be less than 1 mm. According to Schlichting (46:140), the boundary layer thickness for incompressible flow, if defined when $U = .99U_{\infty}$, can be calculated using equation (3.46) at $x = .06$ meters

$$\delta = 5.0 \left[\frac{\mu x}{\rho U_{\infty}} \right]^{1/2} \quad (3.46)$$

Table 3.4. Flat Plate Test Conditions

Test	P o (Bars)	α (degrees)	M	Re -7 ($\times 10^7$) (/m)
O-1	20	0.0	6.0	1.69
O-2	20	5.5	5.26	2.23
L-1	20	0.0	6.0	1.69
L-2	10	0.0	6.0	0.844
H-1	20	0.0	6.0	1.69
H-2	10	0.0	6.0	0.844

where O - Oil flow test
L - Liquid crystal test
H - Heat transfer test

Table 3.5 shows the resulting calculated boundary layer thickness using eqn (3.46). The boundary layer thickness

was calculated at the appropriate test conditions using the numerical code explained in the computational effort, and the results are very similar to those from eqn (3.46).

Table 3.5. Boundary Layer Thickness

	δ (mm)
Po = 20 bar, Re = 1.69×10^7 /m	.3
Po = 10 bar, Re = $.844 \times 10^7$ /m	.5

3.7.1 Oil Flow Results

Figure 3.11 shows the results of the oil flow study on the flat plate at Mach = 6, Re = 1.69×10^7 /m and Po = 20 bar. The oil flow photograph shows the entire flat plate model with the direction of the flow being from left to right. At Mach = 6, most of the limiting surface streamlines are straight and parallel. The Mach 6 case was repeated many times because the results were not reproducible. Some photographs showed the flow as totally straight and parallel while some photographs showed some bending of the streamlines at the rear edges of the plate. However, the bent streamlines sometimes appeared on the right rear edge of the plate, and then the next test they appeared on the left rear edge of the plate. In conclusion, the flow near the edges of the plate at Mach 6 seems to be highly unsteady, but for most of the plate, there is parallel flow at Mach = 6.

Figure 3.12 shows the results of the oil flow study at Mach 5.26, $Re = .844 \times 10^7 / m$ and $Po = 20$ bar. In the center of the plate, the streamlines are straight and parallel. However, toward the edges, the streamlines bend toward the edges of the plate. This occurs since the plate is at an incidence and the flow spills over the sides of the plate.

3.7.2 Sublimation Results

The sublimation test did not produce much information. For all the test cases, sublimation only occurred at the leading edge of the flat plate. This indicates that the end of transition for each of the flow cases, occurs farther downstream than 150 mm, the edge of the plate. The results obtained are consistent with the findings of previous studies (15:F10-F12; 14:F20-F21; 31:110).

3.7.3 Liquid Crystal Results

The liquid crystal technique worked well, but some difficulties arose in trying to record the data. The photographs that recorded the color changes were very dark. There was very little contrast between the colors. The use of the digital image processing would probably make the reading of the colors easier. A strobe light was initially used to illuminate the model for photographic purposes. The strobe light proved to be inadequate as it did not uniformly illuminate the model and caused a large glare spot in the center of the model. One 1000 watt lamp was used next, but it did not produce enough light to obtain a good picture.

Finally, two 1000 watt lamps were used to illuminate the model. The lamps were turned on after the model was injected to keep the time that the model is illuminated down to a minimum. The ejector was run for approximately 15 seconds to verify that the two lamps did not heat the model enough to cause color changes during test conditions. The time of a actual test is less than 13 seconds. Although no color changes were detected during this preliminary time, the lamps were probably adding a small unknown amount of heat to the model. Future tests with liquid crystals need to use a different light source; one that has more illumination power, yet produces less heat.

The coax gage was referenced to the ambient temperature during the calibration. The calibration and test photographs were taken on the same roll of color film and developed at the same time so that the correlation between temperature to color would still be valid.

The surface of the liquid crystal is visually marred at the junction of the plexiglas and stainless steel. Apparently the epoxy glue used to fill the crack did not cure properly after application and the glue spreads into the liquid crystal layer. This did not disturb the flow, but just disturbed the visualization of the colors near the material boundaries.

One difficulty arose in the data reduction method used for the liquid crystal technique. This difficulty was in

determining the temperature of the surface of the model at time $t = 0$, just before injection of the model. The coax gage was not connected during the tests, but its voltage output was recorded before the tunnel was started to obtain the surface temperature of the model at ambient conditions. Later, from the thin film gage heat transfer tests, it was found that the model surface is cooled several degrees when the tunnel ejector is started - so the actual surface temperature of the model at the start of the test is quite lower than that at ambient conditions. The temperature of the model at time $t = 0$ could not be ascertained from the liquid crystals for the temperature was too low for the appearance of any color. Therefore, the initial temperature was obtained from the coax gages in the quantitative heat transfer test. Although the zero data from one test (H-1) is used in another test (L-1), this will introduce only a very small error to the liquid crystal results since the startup and initial conditions of the tunnel were the same for both tests.

The results of the liquid crystal test at $Po = 20$ and 10 bars is shown in Figures 3.13 and 3.14. Theoretical results obtained from eqns (3.12) and (3.14) are also plotted with the experimental data. The experimental errors associated with the liquid crystal tests are 8% for the $\log(Rex)$ and 5% for the Stanton number calculations. The results of the liquid crystal tests match very well with the

theoretical results. A check on the validity of the constant heat flux assumption could not be made using liquid crystal data since it was impossible to obtain temperature versus time data at a constant location. This is due to the limited calibration information. The validity of this assumption will be examined in the next section using the thin film gage data since the heating characteristics of the model are the same, just the method of obtaining the data are different.

3.7.4 Heat Transfer Results

Two thin film gage ceramic pieces were constructed as specified in Figure 3.6. Although only one piece was needed, the second was made in case the first piece was broken during testing. The first piece had thin film gages of 4 mm in length. The second piece had thin film gages of 2 mm in length. The 4 mm gage length piece was used in this test. The second piece, because of the shorter gage length, would be better suited for heat transfer measurements in three dimensional flows.

The film coefficient of resistance calibration data for the 4 mm thin film gages are shown in Table 3.6 and plotted in Figures 3.15 through 3.20. In Table 3.7 are the values of the film coefficient of resistance and other values obtained from the film coefficient of resistance data using a least squares algorithm for the 4mm long gages. The least

squares algorithm solves for the coefficients of eqn (3.47) which corresponds to eqn (3.33).

$$\Delta R = A_0 + A_1 \Delta T \quad (3.47)$$

where A_0 is the intercept of the line and should be approximately zero.

$$\Delta R = R - R_{REF}$$

$$\Delta T = T - T_{REF} \quad (3.48)$$

$$A_1 = \frac{\alpha R_{REF}}{R} = \text{slope of the line}$$

and F is a correlation coefficient that indicates how well the data matches the resulting equation of a straight line. Table 3.8 lists the film coefficient of resistance calibration data for the 2 mm thin film gages, and the same data is plotted in Figures 3.21 through 3.26. The second set of data in Table 3.6 and Table 3.8; gages 25, 26, and 27, correspond to the small gages made for the determination of the ceramic thermal product in the CT-2 tunnel. The value of the thermal product for the 4 mm gage ceramic piece was determined in CT-2 and is $1950.0 \text{ J/m}^2 \text{ }^{\circ}\text{K sec}^{1/2}$. For the 2 mm gage ceramic piece, the thermal product is equal to $2100.0 \text{ J/m}^2 \text{ }^{\circ}\text{K sec}^{1/2}$. The value of the film coefficient of resistance and other output from the least squares algorithm are listed in Table 3.9. The computer program with the least squares algorithm is listed in Appendix J.

The equipment setup is shown in Figure 3.27. The large box on the right contains the constant current generator,

100 gain amplifier, wheatstone bridge, electrical analog circuits, and the parabolic voltage generator. The next set of boxes, stacked four high, are an additional 16 adjustable gain amplifiers. The next piece of equipment is the medium speed data acquisition system with a maximum of 16 data channels, and then the computer console was used to start the acquisition program on the PDP computer. The heat transfer flat plate model installed in the tunnel is shown in Figure 2.28. The coax gages are referenced to an ice bath for the heat transfer tests.

Several complications arose during the initial portion of this testing period. There was initially a tremendous amount of noise in the data. This noise was decreased by grounding all the equipment in the data acquisition chain together and grounding the cables from the gages to the tunnel floor. The noise that remains is nearly the same order of magnitude as the data. The noise varies for each gage, but at worst has an unamplified magnitude of 0.2 millivolts, and has a frequency of 50 hertz. The magnitude and frequency of the noise did not change after all the lights and unnecessary equipment were shut off.

The second complication was due to the fact that a negative heat flux occurred on the surface of the plate prior to injection of the model. This negative heat flux occurs when the tunnel ejector is started and the test section is evacuated. This negative heat flux is several

times the magnitude of the data to be recorded. Because of this problem and the relatively large amount of noise present, the integration of the temperature trace using the analog circuit would be too inaccurate so could not be used. The numerical integration method was the only possible way to interpret the data under these conditions. This method is complicated by the reference shift during the test.

Before any good tests could be performed the air compressor for the tunnel broke. It was initially thought that the compressor would not be fixed in a short amount of time so testing was stopped and the medium speed data acquisition system was given to another student. However, the compressor started working after a couple days, so oscilloscopes were used to photograph the temperature trace so some data could be obtained. However, an accurate recording of the reference shift could not be obtained when using the oscilloscope. As a last resort, the high speed data acquisition system was obtained and two tests were performed and the data successfully recorded. Due to time limitations, only the two coax gages and ten thin film gages were recorded during each test. The final equipment setup was similar to that shown in Figure 3.27, except that the high speed data acquisition system was used, and only 12 additional amplifiers were available for the tests.

An example of the temperature trace obtained from a thin film gage is shown in Figure 3.29. The 50 hertz noise

was "smoothed" using an averaging technique. (A least squares algorithm was used initially, but gave incorrect results.) The data was averaged over one period of the noise. An example of the data after smoothing is shown in Figure 3.30. The averaging algorithm is shown in Appendix K. A comparison between raw versus smoothed data shows the smoothed data accurately represents the real data. The raw and smooth data for each channel was plotted and it was verified that the "real" data was kept intact before the numerical integration was performed.

A sample heat transfer rate versus temperature curve is shown in Figure 3.31. The curve shows a rise in heat flux to some maximum and then a decrease in the heat flux corresponding to the fact that the plate is heating up. The isothermal heat flux is obtained from the second portion of the curve and extrapolated back to the temperature of the plate at time = 0. An example of the heat flux versus temperature curve for the two data reduction methods are shown in Figures 3.22 and 3.33. These plots show the rise in heat flux, but the test time was apparently too short to obtain the second portion of the curve. For this reason, the value of the heat flux used to calculate the Stanton number is obtained near the end of the trace. Due to this reasoning, the Stanton number is expected to be lower than expected.

To verify the accuracy of the assumption of constant heat flux, the square of the surface temperature is plotted versus time in Figure 3.34 for one of the gages. If the initial portion of the curve is omitted because of the model injection, the trace is indeed a straight line for the period of the test, approximately .6 seconds.

Unfortunately, most of the data from the coax gages were unusable. An example of a trace is shown in Figure 3.35. Since a very small temperature increase was expected during the test, approximately 1 °C, the amplifiers were set for a gain of 1000, but this was not enough amplification to distinguish the real signal from the noise. A comparison between the thin film gage and the coax gage should be done at test conditions that will produce higher heating rates, ie. higher chamber pressure and lower Mach number.

The computer programs used to convert the data from the VKI PDP computer acquisition file is listed in Appendix K. Appendix L contains the input data files needed to convert the data from digital units to physical units. Appendix M lists the data conversion program, Appendix N is the numerical integration program for the thin film gages. Appendix P lists the program used to calculate the heat flux for an isothermal flat plate. Although not used in this study, Appendix O contains the temperature reconstruction program and Appendix R the coax gage reduction program.

The results of the heat transfer test at $P_o = 20$ and 10 bars are shown in Figures 3.36 and 3.37. These results show the beginning of transition. There is very little difference in the results from the direct method when compared to the results of the indirect method. The experimental errors in the heat transfer test are large, approximately 12%, due to the low amount of heat flux measured. The results of the heat transfer test are quite lower than the results from the theoretical equations (3.12) and (3.14).

Figure 3.36 shows the onset of transition for $Re = 1.69 \times 10^7 / m$ could be at $\log(Rex) = 6.26$ ($x = 107$ mm). However, what is missing from the figure is the fourth data point corresponding to $\log(Rex) = 6.19$ ($x = 91$ mm). The gain on the amplifier was too high for the heat flux trace that was present so no quantitative data could be taken. It is possible that it is just a stray point due to a bad gage, but it could also be an indication of transition.

Figure 3.37 shows the results for $Re = .844 \times 10^7 / m$. Again the fourth data point corresponding to $\log(Rex) = 5.89$ and $x=91$ mm is missing due to a high signal. Because of the lower Stanton numbers after transition, it appears that the position of fully turbulent flow is further downstream than for the higher Reynolds number case. Since no other data is available to determine if the fourth data point is bad, the beginning of transition for both Reynolds number cases

occurs between $x = 83$ mm and 91 mm. More data points need to be taken to better define the location of transition.

3.8 Flow Interaction

At Mach numbers above 4, the most severe problems of atmospheric flight are associated with viscous-inviscid interactions (33:177). Cruise vehicles and lifting re-entry vehicles have highly complex, three-dimensional configurations in which exist many regions of high compression that can cause boundary layers to separate. The flow reattachment that follows this separation, causes a rise in heat rates that can far exceed those for an attached boundary layer. A possibly more serious viscous interaction problem is the impingement of shock waves generated by the forebody resulting in local heat rates that may be many times larger than stagnation point values. However, unlike stagnation point heating where the location is obvious, the problem with complex configurations is to determine where the high heat rates are likely to occur, as well as their magnitude.

This study will examine one viscous interaction problem area, that of flow interaction past a blunt fin. The interaction of the bow shock of a fin with the boundary layer on a plate can cause widespread separation and vorticity of a three-dimensional nature. Adjacent to the fin, parallel, finely spaced embedded vortices may form and cause striation heating. The embedded vortices produce highly localized heating rates that are significantly greater than heating in adjacent undisturbed areas. Oil

flow visualization tests were conducted to examine the general structure of the flow interaction region. Sublimation tests were conducted to determine the global heating of the interaction area. The information obtained by first employing sublimation, rather than heat transfer gages, can be used to better determine where to locate those thin film or coax gages in future tests.

3.8.1 Topological Rules

It has been postulated by Peake and Tobak (41) that all cases of three dimensional flow separation and reattachment can be described mathematically. Using

"the assumption of continuous vector fields of skin friction lines and external flow streamlines, when coupled with simple laws of topology, provides a flow grammar"

which enables one to create plausible flow structures. The elementary singular points of the flow field: nodes, spiral nodes (foci), and saddlepoints, can be categorized mathematically. Therefore,

"the types of singular point, their number, and the rules governing the relations between them, can be said to characterize the pattern."

Figure 3.38 shows the structure of these elementary singular points; the solid lines represent the skin friction lines while the dashed lines represent the surface vortex lines which are orthogonal at every point to the system of skin friction lines. By utilizing these ideas, mean flow characteristics and flow mechanisms can be deduced when wind tunnel results give insufficient information.

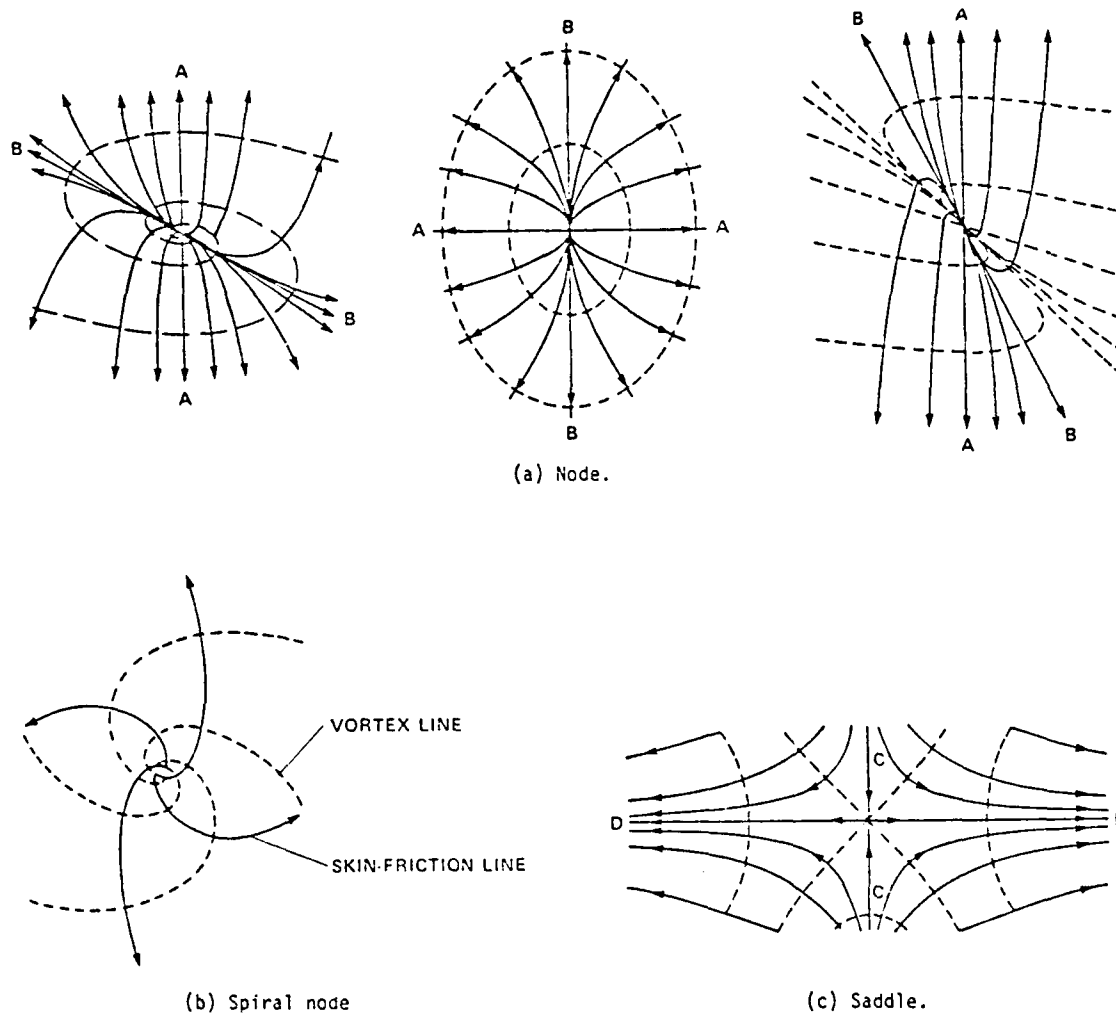

Figure 3.38. Singular Points

Peake and Tobak (41:1-5) list five special topological rules that apply to flow past wings and bodies at angle of attack. Of these five rules, only three could apply to the flow field in this study and are listed here:

1. Skin friction lines on a three dimensional body:

$$\sum_N - \sum_S = 2 \quad (3.49)$$

2. Skin friction lines on a three-dimensional body B connected simply without gaps to a plane wall P that either extends to infinity both upstream and downstream or is the surface of a torus:

$$\left[\sum_N - \sum_S \right]_{P+B} = 0 \quad (3.50)$$

3. Streamlines on a two dimensional plane cutting a three dimensional body:

$$\left[\sum_N + 1/2 \sum_{N'} \right] - \left[\sum_S + 1/2 \sum_{S'} \right] = -1 \quad (3.51)$$

However, in terms of this study, more information is required before the method of topology can be really useful. Namely, the flow on the fin and the flow on the plate near the trailing edge of the fin needs to be studied to get an approximate picture of the entire three dimensional flow pattern before this method of using topological rules can be utilized.

3.8.2 Flow Ahead of the Fin

3.8.2.1 Flow Structure

High speed flow over a blunt fin on a surface results in a very complex, inviscid-viscid interaction flow field. The bow shock from the fin causes the boundary layer to separate from the surface ahead of the fin, resulting in a separated flow region composed of horseshoe vortices near the surface and a lambda-type shock pattern in the plane of symmetry ahead of the fin. Experiments completed by Kaufmann, Korkegi, and Morton (26:5) reveal that the separated flow is very unsteady. Shadowgraph photographs were blurry until the exposure time was decreased to times on the order of microseconds. This is attributed to a "pulsating, scavenging action of the horseshoe vortices" which results in large oscillations of the impinging shock wave.

Korkegi states that the characteristics of skewed shock induced separated regions (32:599) do not exhibit any basic differences between laminar and turbulent flow for comparable extents of separation. (However, the adverse pressure gradients needed for extensive separation, are much larger for turbulent than for laminar flow, and the detail of the flow structure differs because of turbulent mixing in one case and molecular mixing in the other.) Therefore, it is possible to define the structure of the separated flow region, resulting from the interaction of a skewed shock

wave with either a laminar or turbulent boundary layer. This reasoning, which is developed from separated regions induced by skewed shocks, is extended to separated regions induced by bow shocks.

One possible interaction flow field of a separated region induced by a fin bow shock is shown in Figure 3.39 (54:47). This flow field is proposed by Winkelman for turbulent flows and is similar to two dimensional separated flows ahead of steps or ramps. The pressure rise across the fin bow shock presents a strong adverse pressure gradient to the boundary layer flow on the flat plate surface, causing the boundary layer to separate from the surface and form a region of reverse flow adjacent to the plate surface. The effects of the pressure rise are propagated upstream through the reverse flow region. The reverse flow forms several horseshoe vortices in which the flow quickly curves downstream, away from the plane of symmetry (26:4). A nodal point of attachment is postulated to exist between the primary and secondary separation lines, or separated regions. The nodal point is indicated to be produced by adjacent regions of recirculating vortex flow. The reverse flow in the vortices is fed by the separated stream flow and spirals downstream very rapidly. Severe heating rates are

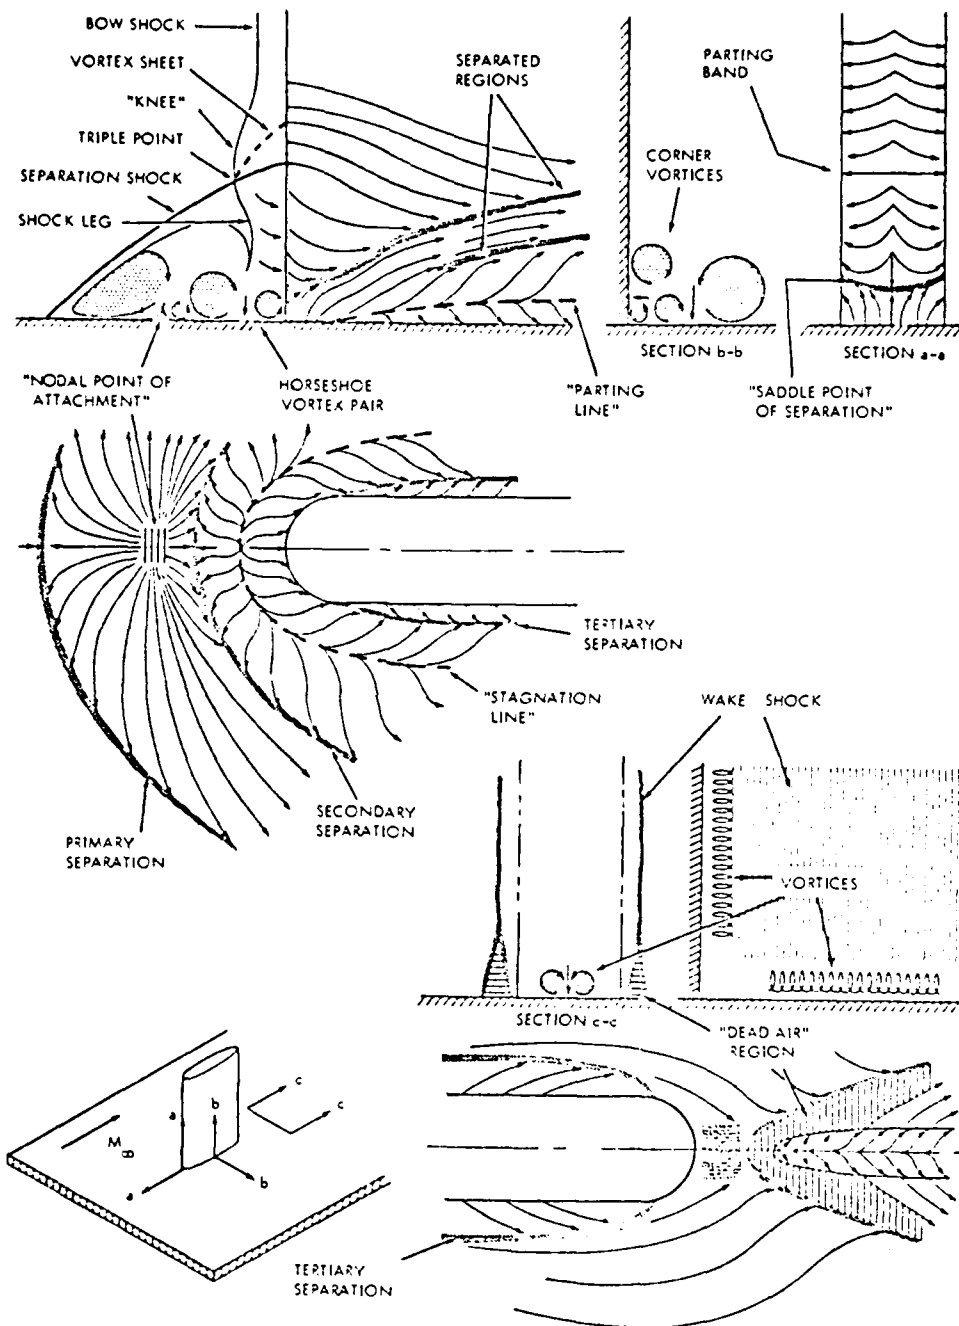

Figure 3.39. Flow Interaction Model

caused by these vortices bringing high energy air flow into close proximity with the surface. This has been shown experimentally in that the heat transfer rates are shown to peak at reattachment regions following a region of separation. In a skewed shock interaction (32:599) in laminar flow, Figure 3.40, Korkegi shows that the two peaks in the heat transfer rate are associated with the two reattachment lines, denoted by R, in the flow interaction region.

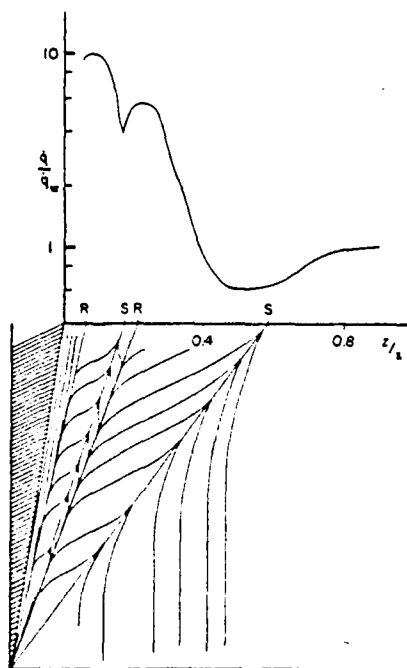

Figure 3.40. Spanwise Heat Transfer for Laminar Flow
 $M = 20$, Wedge Angle = 10°

3.8.2.2 Separation Distance

The separation distance upstream of a fin leading edge is found to scale with fin diameter for conditions when the

fin is slender, is at zero degree incidence, and its diameter is larger than the boundary layer thickness (55:31). As in two dimensional flow, this distance is considerably greater for laminar than for turbulent flow (30:361). For laminar flow, this separation distance is Mach number and Reynold's number dependent. Limited data indicate that the extent of entirely laminar separation ahead of a fin increases with increasing Reynold's number. Laminar separation lengths exceeding six diameters have been observed (55:24) for both Mach 3 and Mach 5 flows.

However, separation is a strong disturbance to a laminar boundary layer and causes earlier transition than for attached undisturbed boundary layers. In this case, transition can occur either ahead of the separated location (turbulent separation) or in the free shear layer bounding the reverse flow region ahead of the fin (transitional separation). The extent of transitional separation diminishes toward the turbulent value as the separation location approaches the undisturbed boundary layer transition location, as can be seen in Figure 3.41 (26:25).

For turbulent flow, the separation distance appears to be insensitive to Reynold's number. The magnitude of the separation distance is usually twice the diameter of the fin, for cases when the fin diameter is larger than the boundary layer thickness.

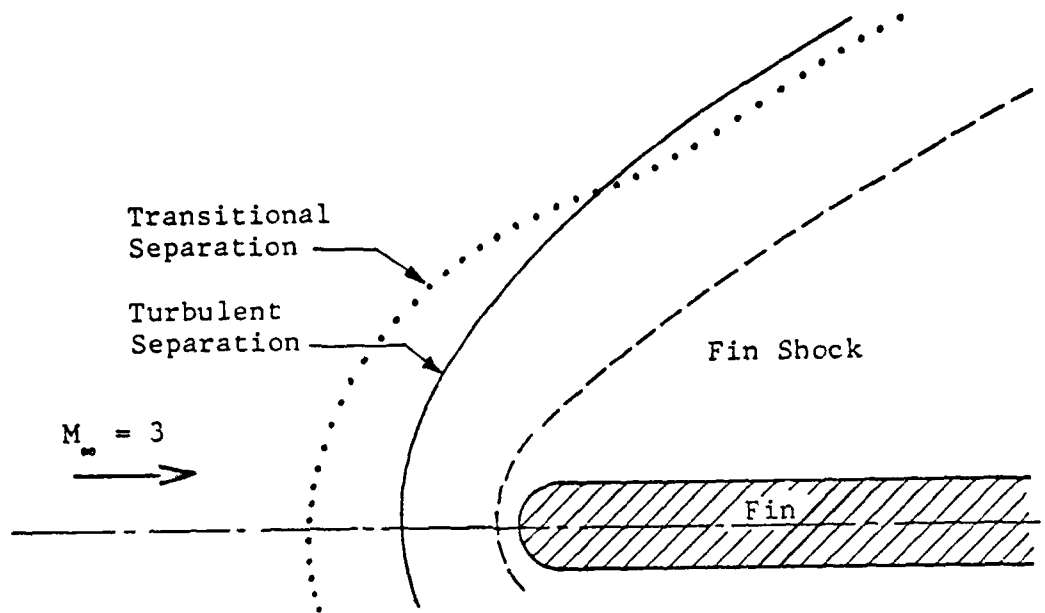

Figure 3.41. Transitional and Turbulent Separation Line Shapes

The effect of leading edge sweep on the extent of the interaction has been investigated by Price and Stalling (43) for supersonic turbulent flow. They find that for sweep angles from 0° to 30° there is a sharp decrease in extent of separation, but no change in the first peak pressure. For larger sweep angles, both decrease until they are barely perceptible at 75° .

For a fin incidence angle of 10° (6:698), Reynold's number affects both the scale of the separation and the surface streamline patterns aft of the separation. Placing

the fin at an incidence of 10° also resulted in a region of increased heat transfer which originated near the leading edge and extended the length of the fin.

Price and Stalling (43) have studied the effect of fin height on turbulent flows past protuberances. Their results were a little surprising in that they found no difference in leading edge separation distances when the fin height varied for lengths smaller than the boundary layer height to many times the extent of the boundary layer.

3.8.3 Embedded Vortices

Striation heating is attributed to streamwise vortex formations embedded in the boundary layer which produce locally enhanced heating levels. Persen (28:1) has suggested that the formation of the embedded vortex system

"is connected with the stability of curved flow, i.e., flows where the streamlines are non-parallel, exhibit a curvature, a pressure gradient and a velocity gradient."

No agreement exists on a universal explanation of regularly spaced streamwise embedded vortices, but several mechanisms have been identified by researchers. One of these mechanisms produce what is known as Goertler vortices. Schlichting (46:526,532-535) describes these streamwise vortices which can occur in boundary layer flow over concave walls. In such boundary layers, the fluid particles near the wall experience a lower centrifugal force than those nearer the boundary layer edge. Such flows are inherently unstable and provide a mechanism for transition from laminar

to turbulent boundary layer flow. When a critical Reynold's number is exceeded, small disturbances will amplify and form a system of streamwise vortices within the boundary layer, as shown in Figure 3.42.

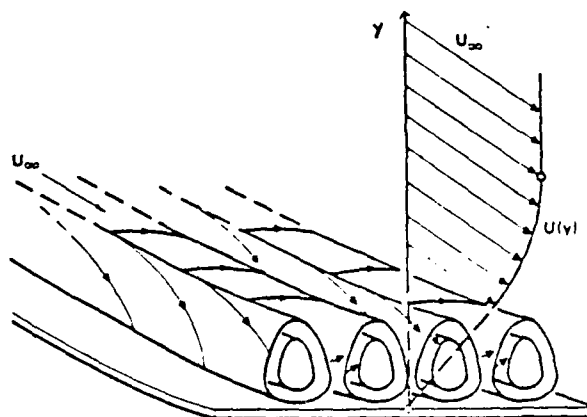

Figure 3.42. Goertler Vortices

It has been suggested by Kipp and Helms (28:3) that a separation bubble resulting from a shock - boundary layer interaction can cause a concave turning of the boundary layer flow, thereby initiating Goertler vortices.

3.9 Results of the Flat Plate with Blunt Fin Study

Table 3.10 shows the test conditions for all the photographs included in this report for tests completed on the flat plate with the blunt fin. Appendix S shows the test conditions and VKI photograph catalog number for every test completed.

Table 3.10. Flat Plate with Fin Test Conditions

3.9.1 Shadowgraph Results

The shadowgraph results were very blurry and did not give very much detailed information. For future studies on a flat plate model, it may be better to use single-pass shadowgraph/schlieren. Since the model is essentially two dimensional, the photographs are too blurry due to the "double" exposure of the double-pass system. Another factor contributing to the blurriness of the photographs was the time of exposure. Previous studies have shown that the three dimensional flow interaction is so unsteady that it requires exposure times on the order of microseconds. The photographs in this study had an exposure time of 10 milliseconds.

However, the photographs did show that the shock originating from the separation region did not impinge on the fins of 0° sweep and 6 mm in height. It is possible that the flow structure on the plate could change if the fin was made taller and a shock impingement on the fin occurred.

3.9.2 Oil Flow and Sublimation Results

Several photographs of the results from oil flow and sublimation tests are shown in Figures 3.43 through 3.66. The oil flow photographs were taken after the tunnel was stopped and accurately represent the oil flow pattern in the tunnel during the tests except for some oil splattering and spreading of accumulation lines.

In the interaction oil flow photographs of the fins with zero sweep, there appears to be a "bump" present in the secondary separation line, as shown for example in Figure 3.48. This bump is a real phenomena, as its appearance is repeatable. This bump is not really evident in the sublimation photographs. No similar bump was found in a review of the limited references of blunt fin interaction in laminar flow. This bump does not appear to be caused by fin height, as can be seen in a comparison of Figures 3.43 and 3.44. Since a sign of early transition caused by the separated flow occurs on the primary separation line, (refer to Figure 3.41 and section 3.8.2.2), this bump does not indicate early transition since it occurs on the secondary separation line. The bump moves downstream (becomes less noticeable) as the Reynolds number increases, as can be seen in Figures 3.44 and 3.48. It is evident only on the expansion side of the fin when the fin is at incidence. The cause of the bump could be an interaction between the vortices on either side of the secondary separation line, the bump being produced when the vortex closer to the fin is stronger than the other vortex and dominates over the weaker vortex's flow area.

The separation distance ahead of the fin, l , non-dimensionalized with the fin diameter, d , is plotted against the Reynold's number based on the distance from the plate leading edge to the separation line, in Figures 3.67 through

3.69. The figures show the l/d distance for a fin incidence of 0, 15, and 40°. The separation distance is measured from the fin leading edge to the middle of the primary separation line or region. The errors in these measurements vary according to the amount of oil spreading that occurred on the primary separation line. For the short fin height at 0 and 15° incidence, the error corresponds to ± 2 l/d or 4%. At 40° incidence and for all the $h=15$ mm tests, the error corresponds to ± 3 l/d or 5%. A trend that is apparent is that the separation distance increases as the sweep angle is decreased. This is in agreement with the results found by Price and Stallings (43). A Reynolds number dependence on separation distance could not be determined from the oil flow photographs.

There appears to be no effect of fin height on the separation distance for zero sweep as shown in Figures 3.67 and 3.68, for incidence angles of 0 and 15°. This is also shown in the oil flow photographs, Figures 3.42 and 3.44, for 0° incidence. Another effect of fin height can also be seen in these figures. The secondary separation line is much blunter ahead of the fin leading edge for the taller fin. This bluntness can also be seen in Figure 3.48. For a fin incidence angle of 40°, there is a strong effect of fin height for the heights studied in this test, the separation distance increased dramatically when the fin height was increased from 6 to 15 mm, as can be seen in Figure 3.69.

The oil flow/sublimation photographs, Figures 3.45/3.46 and 3.59/3.60, compare the effect of fin height for a fin of 40° incidence and zero sweep. The flow patterns are also very different. In the $h = 6$ mm case, four reattachment regions are apparent. However, if the height of the fin is increased, there are only three reattachment regions. It is hypothesized that the flow passing over the fin combines with the vortices forming the second reattachment region causing an instability, thereby causing an additional vortex pair to form another reattachment region.

Changing the Reynolds number appears to have some effect on the flow patterns, other than increasing the separation distance. The main difference is the change of the "bump" and this can be seen by comparing the oil flow photographs, Figures 3.44 and 3.48, and 3.47 and 3.50. Slight differences in the flow structure can be seen in the oil flow photographs but the corresponding sublimation photographs do not show the same detail.

Kipp and Helms (28:8) show an example of striation heating caused by embedded vortices on the side fuselage of a Space Shuttle orbiter model during a thermal mapping wind tunnel test. (Kipp and Helms reference their Reynolds number to a characteristic length.) The striations were not present at Mach 10, $Re_{\infty} = 2.4 \times 10^6$ and $\alpha = 20^\circ$, but the streaks appeared when the angle of attack was increased to 40° . Striations also appeared at Mach 6, $Re_{\infty} = 2.7 \times 10^6$ and

$\alpha = 40^\circ$ and increasing the Reynold's number at Mach 6 to $Re_\infty = 7.3 \times 10^6$ resulted in a larger number of striations. These streaks from Kipp and Helms (28) look very similar to the streaks shown in Figure 3.66 which were produced in a similar test regime of Mach 6, $Re_\infty = 8.66 \times 10^6$, fin sweep angle of 75° and a fin incidence angle of 40° . Figure 3.64 also shows that the streaks begin to appear when the fin sweep is 60° . However, when the fin is at an incidence angle of 15° , there is no indication of striation heating at sweep angles of 60 or 75° , as can be seen in Figures 3.56 and 3.58.

3.9.3 Proposed Flow Interaction Models

Possible models for the flow interaction region have been developed from the oil flow and sublimation photographs. The details of the models are dependent upon the fin incidence and fin sweep. The models are sketched in Figures 3.70 through 3.74. The models are characterized by a nodal point of attachment and counter-rotating vortex pairs that create the alternating regions of separation and reattachment.

IV. Overall Results

The experimental flat plate data obtained from this study are compared to the results of the thesis computer program. The results from the numerical code are for the fully laminar case. The comparisons are completed for two Reynolds numbers, $.844 \times 10^7 / m$ and $1.69 \times 10^7 / m$, and are shown in Figures 3.75 and 3.76, respectively.

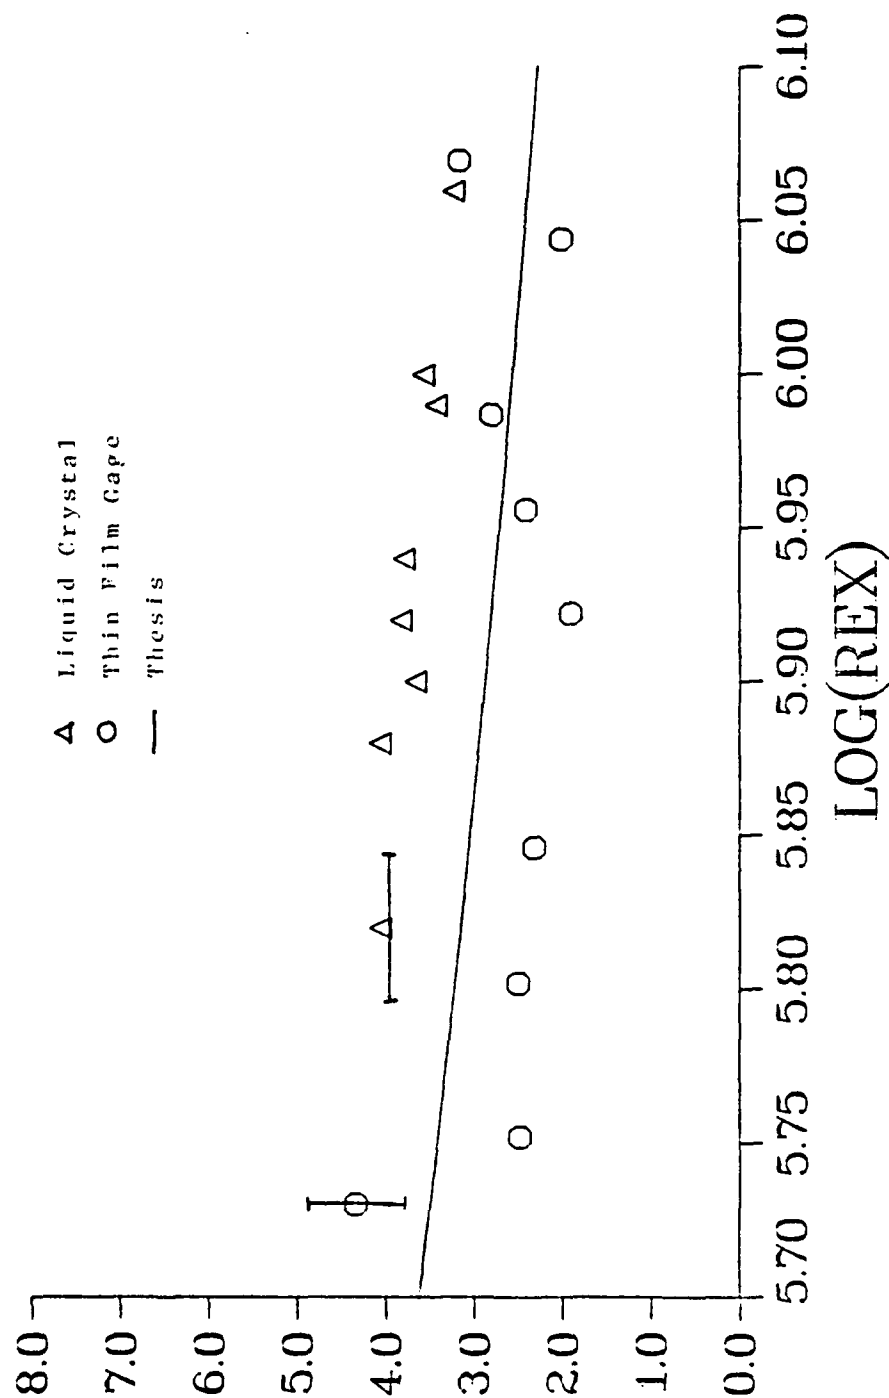

The lower Reynolds number comparison, Figure 3.75, shows the experimental data differing 20% with the numerical results. The liquid crystals being 20% high and the thin film gage being 20% low. The results from the higher Reynolds number case, Figure 3.76, agrees much better with the numerical code. This is in part due to the higher signal that is recorded at the higher Reynolds number.

V. Overall Conclusions

The modification of using the Thomas algorithm in solving the momentum and energy equations instead of using the optimized successive over-relaxation method improved the efficiency of the program for large grids or when high accuracy is required. The steady eddy viscosity turbulence models; Van Driest and Chapman for the inner region, and mixing length and Clauser for the outer region, when compared in a compressible case, showed very little difference in the heat transfer rates (Stanton number).

The liquid crystal results agreed with theory very well, but the method did not show any indication of transition. This is probably due to the poor quality of the color photographs that were used to record the information. The thin film gage data were quite low with respect to theoretical results, and this is due in part to the short testing time.

A large amount of useful information was obtained with the oil flow and sublimation photographs of the flow interaction region of the fin on the flat plate. It was found that the separation distance upstream of the fin increased as the sweep angle is decreased. Striation heating appeared in two cases that were examined. The flow regime that produced the striation heating was Mach 6 flow, $Re = .844 \times 10^7 / m$, fin with 60° or 75° sweep and 40°

incidence. Several flow interaction models were suggested for the different test cases.

The heat transfer results obtained from the numerical technique and experimental technique were compared. Agreement to within 20% exists for the lower Reynolds number comparison. At the higher Reynolds number cases, the agreement between numerical data and experimental data are very good.

VI. Recommendations

Several recommendations for future study have been realized during the course of this project. They are:

1. Modify the steady turbulence model to an unsteady model using the method of Lorber (38).
2. Generate a grid to account for the increase in the boundary layer due to turbulence.
3. Add to the program an adaptive grid method optimized for minimizing truncation error.
4. Extend the code to axisymmetric problems, ultimately to three dimensional cases.
5. Modify the code to solve the momentum and continuity equations in a coupled manner, such as the Davis-Coupled Scheme, to accelerate convergence of the lagged coefficients (3:339).
6. Place the fin closer to the leading edge of the plate (to obtain fully laminar flow) to determine if the "bump" seen in the oil flow photographs is caused by transition or another phenomena.
7. Continue the study of the three dimensional flow interaction region with different shaped fins, ie., taller, wider, sharp edged, using flow visualization and schlieren with shorter exposure times.
8. Expand the flow visualization area of study to include

the fin and the plate area near the trailing edge of the fin to develop a flow interaction model using topological rules (41).

9. Continue the study of the three dimensional flow interaction region using liquid crystals and digital image processing.
10. Obtain quantitative data on the three dimensional flow interaction region using coax gages or thin film gages.
11. Study the heat transfer rates on the fin.
12. Design a new pressure rake to permit calibration of the wind tunnel farther than 143 mm from the nozzle exit.

Appendix A

Time and Mass-Weighted Averaging

A combination of conventional time averaging and mass-weighted averaging (7:49-55) has been used in the development of the governing equations for turbulent boundary layers. The time averaged variables are defined as follows:

$$\bar{\rho} = \bar{\rho} + \rho'' \quad (A.1)$$

$$\bar{P} = \bar{P} + P'' \quad (A.2)$$

where $\bar{\rho}$ and \bar{P} are the time averages of the bulk density and pressure, respectively, and ρ'' and P'' are the superimposed density and pressure fluctuations, respectively. The time average or "mean" of any quantity $q(t)$ is defined by

$$\bar{q}(t) = \lim_{\Delta t \rightarrow \infty} \frac{1}{\Delta t} \int_0^{t+\Delta t} q(t) dt \quad (A.3)$$

For a fluctuating quantity $q''(t)$, the mean is zero by definition, ie.,

$$\bar{q''(t)} = 0 \quad (A.4)$$

therefore,

$$\bar{\rho''} = 0 \quad (A.5)$$

$$\bar{P''} = 0 \quad (A.6)$$

The mass-weighted variables are defined as follows:

$$u = \tilde{u} + u' \quad (A.7)$$

$$v = \tilde{v} + v' \quad (A.8)$$

$$H = \tilde{H} + H' \quad (A.9)$$

$$T = \tilde{T} + T' \quad (A.10)$$

A mass-weighted mean quantity is defined as:

$$\tilde{q} = \frac{\bar{\rho}q}{\bar{\rho}} \quad (A.11)$$

where the bar denotes conventional time averaging and the tilde denotes mass-weighted averaging. A consequence of combining the time and mass-weighted averaging definitions for the product ρq :

$$\rho q = (\bar{\rho} + \rho'')(\tilde{q} + q') = \bar{\rho}\tilde{q} + \bar{\rho}q' + \rho''\tilde{q} + \rho''q' \quad (A.12)$$

is when the time average is taken, eqn (A.12) becomes

$$\bar{\rho}q = \bar{\rho}\tilde{q} + \bar{\rho}q' + \overline{\rho''q'} \quad \text{since } \bar{\rho''} = 0 \quad (A.13)$$

$$\bar{\rho}q = \bar{\rho}\tilde{q} + \bar{\rho}q' \quad \text{since } \bar{\rho} = \bar{\rho} + \bar{\rho''} \quad (A.14)$$

By definition, from equation (A.11), $\tilde{\rho}q = \bar{\rho}\tilde{q}$, therefore

$$\bar{\rho}q' = 0 \quad (A.15)$$

Therefore, by analogy let

$$\bar{\rho}u' = 0 \quad (A.16)$$

$$\bar{\rho}v' = 0 \quad (A.17)$$

$$\bar{\rho}H' = 0 \quad (A.18)$$

$$\bar{\rho}T' = 0 \quad (A.19)$$

Total enthalpy can also be expressed in another form including the static enthalpy.

$$\phi H = h + 1/2 \phi u^2 \quad (A.20)$$

If the total enthalpy, eqn (A.20), is mass averaged,

$$\bar{\phi} H + \phi H' = \bar{\phi} h + \phi h' + 1/2 \phi (\bar{u} u + 2 \bar{u} u' + u' u') \quad (A.21)$$

Taking the mean of equation (A.21) gives

$$\bar{\phi} H = \bar{\phi} h + 1/2 \bar{\phi} u u + 1/2 \overline{\phi u' u'} \quad (A.22)$$

$$H = h + 1/2 \bar{u} u + 1/2 \frac{\overline{\phi u' u'}}{\bar{\phi}} \quad (A.23)$$

Since $H = \bar{H} + H'$, using the definition: $H = h + 1/2 u^2$

$$H = \bar{h} + h' + 1/2 (\bar{u} + u')^2 \quad (A.24)$$

$$\bar{H} + H' = \bar{h} + h' + 1/2 \bar{u} u + \bar{u} u' + 1/2 u' u' \quad (A.25)$$

Solving for H' and substituting eqn (A.23) into eqn (A.25):

$$H' = h' + \bar{u} u' + 1/2 u' u' - 1/2 \frac{\overline{\phi u' u'}}{\bar{\phi}} \quad (A.26)$$

This result will be used later in Appendix B.

Averaging of the Boundary Layer Equations

The boundary layer equations are given as follows. The equation numbers correspond to the number given originally to the same equation in the main body of the report.

continuity

$$\frac{\partial \phi}{\partial t} + \frac{\partial \phi u}{\partial x} + \frac{\partial \phi v}{\partial y} = 0 \quad (2.1)$$

x-momentum

$$\frac{\partial \rho^\# u^\#}{\partial t^\#} + \frac{\partial \rho^\# u^\# u^\#}{\partial x^\#} + \frac{\partial \rho^\# u^\# v^\#}{\partial y^\#} = - \frac{\partial P^\#}{\partial x^\#} + \frac{\partial}{\partial y^\#} \left[\mu^\# \frac{\partial u^\#}{\partial y^\#} \right] \quad (2.2)$$

y-momentum

$$\frac{\partial P^\#}{\partial y^\#} = 0 \quad (2.3)$$

energy

$$\begin{aligned} \frac{\partial \rho^\# H^\#}{\partial t^\#} + \frac{\partial \rho^\# u^\# H^\#}{\partial x^\#} + \frac{\partial \rho^\# v^\# H^\#}{\partial y^\#} = \frac{\partial P^\#}{\partial t^\#} + \frac{\partial}{\partial y^\#} \left[k^\# \frac{\partial T^\#}{\partial y^\#} \right] \\ + \frac{\partial}{\partial y^\#} \left[\mu^\# u^\# \frac{\partial u^\#}{\partial y^\#} \right] \end{aligned} \quad (2.4)$$

Apply mass-weighted averaging on the boundary layer eqns (2.1), (2.2), (2.3), and (2.4).

Continuity

The continuity equation (2.1) after mass-weighted averaging becomes

$$\frac{\partial \bar{\rho}^\#}{\partial t^\#} + \frac{\partial \bar{\rho}^\# (\bar{u}^\# + \bar{u}^{\#'})}{\partial x^\#} + \frac{\partial \bar{\rho}^\# (\bar{v}^\# + \bar{v}^{\#'})}{\partial y^\#} = 0 \quad (A.27)$$

Taking the mean of the equation,

$$\frac{\partial \bar{\rho}^\#}{\partial t^\#} + \frac{\partial \bar{\rho}^\# \bar{u}^\#}{\partial x^\#} + \frac{\partial \bar{\rho}^\# \bar{u}^{\#'}}{\partial x^\#} + \frac{\partial \bar{\rho}^\# \bar{v}^\#}{\partial y^\#} + \frac{\partial \bar{\rho}^\# \bar{v}^{\#'}}{\partial y^\#} = 0 \quad (A.28)$$

But, noting that

$$\overline{\bar{\rho}^\# \bar{u}^{\#'}} = 0 \quad \text{and} \quad \overline{\bar{\rho}^\# \bar{v}^{\#'}} = 0 \quad (A.29)$$

Which results finally in the time and mass-weighted averaged continuity equation:

$$\frac{\partial \bar{\rho}^\#}{\partial t^\#} + \frac{\partial \bar{\rho}^\# \bar{u}^\#}{\partial x^\#} + \frac{\partial \bar{\rho}^\# \bar{v}^\#}{\partial y^\#} = 0 \quad (A.30)$$

x-momentum

The x-momentum equation (2.2) after mass-weighted averaging becomes

$$\begin{aligned} & \frac{\partial \rho \# (u \# + u \#')}{\partial t \#} + \frac{\partial \rho \# (u \# u \# + 2 u \# u \#' + u \# u \#')}{\partial x \#} + \frac{\partial \rho \# (u \# + u \#') (v \# + v \#')}{\partial y \#} \\ &= - \frac{\partial P \#}{\partial x \#} + \frac{\partial}{\partial y \#} \left[\mu \# \frac{\partial (u \# + u \#')}{\partial y \#} \right] \end{aligned} \quad (A.31)$$

Taking the mean of the equation,

$$\begin{aligned} & \frac{\partial \rho \# u \#}{\partial t \#} + \frac{\partial \rho \# u \#'}{\partial t \#} + \frac{\partial \rho \# u \# u \#}{\partial x \#} + \frac{\partial 2 \rho \# u \# u \#'}{\partial x \#} + \frac{\partial \rho \# u \# u \#'}{\partial x \#} + \frac{\partial \rho \# u \# v \#}{\partial y \#} \\ &+ \frac{\partial \rho \# u \# v \#'}{\partial y \#} + \frac{\partial \rho \# u \# v \#'}{\partial y \#} + \frac{\partial \rho \# u \# v \#'}{\partial y \#} = - \frac{\partial P \#}{\partial x \#} \\ &+ \frac{\partial}{\partial y \#} \left[\mu \# \frac{\partial}{\partial y \#} u \# (1 + u \#'/u \#) \right] \end{aligned} \quad (A.32)$$

From eqns (A.29) and (A.32) this results finally in the time and mass-weighted averaged x-momentum equation:

$$\begin{aligned} & \frac{\partial \rho \# u \#}{\partial t \#} + \frac{\partial \rho \# u \# u \#}{\partial x \#} + \frac{\partial \rho \# u \# u \#'}{\partial x \#} + \frac{\partial \rho \# u \# v \#}{\partial y \#} + \frac{\partial \rho \# u \# v \#'}{\partial y \#} = - \frac{\partial P \#}{\partial x \#} \\ &+ \frac{\partial}{\partial y \#} \left[\mu \# \frac{\partial}{\partial y \#} u \# (1 + u \#'/u \#) \right] \end{aligned} \quad (A.33)$$

Y-momentum

Taking the mass-weighted average of the Y-momentum eqn (2.3) has no meaning since the pressure is only averaged in time. Therefore taking the time average of the pressure,

$$\overline{\frac{\partial(P\# + P\#')}{\partial Y\#}} = 0 \quad (\text{A.34})$$

and realizing that, $\overline{P\#'} = 0$, results in the time averaged Y-momentum equation:

$$\overline{\frac{\partial P\#}{\partial Y\#}} = 0 \quad (2.14)$$

Energy

$$\begin{aligned} \frac{\partial \rho\# H\#}{\partial t\#} + \frac{\partial \rho\# u\# H\#}{\partial x\#} + \frac{\partial \rho\# v\# H\#}{\partial Y\#} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[k\# \frac{\partial T\#}{\partial Y\#} \right] \\ + \frac{\partial}{\partial Y\#} \left[\mu\# u\# \frac{\partial u\#}{\partial Y\#} \right] \end{aligned} \quad (2.4)$$

Before the energy equation (2.4) is mass-averaged, the right hand side of the equality sign can be rewritten in a more convenient form using $h\# = cp\# T\#$,

$$\text{LHS of (2.4)} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[\frac{k\# \partial h\#}{cp\# \partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\frac{\mu\# \partial (1/2 u\# u\#)}{\partial Y\#} \right] \quad (\text{A.35})$$

Since $h\# = H\# - 1/2 u\# u\#$:

$$\begin{aligned} \text{LHS of (2.4)} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[\frac{k\# \partial H\#}{cp\# \partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\frac{\mu\# \partial (1/2 u\# u\#)}{\partial Y\#} \right] \\ - \frac{\partial}{\partial Y\#} \left[\frac{k\# \partial (1/2 u\# u\#)}{cp\# \partial Y\#} \right] \end{aligned} \quad (\text{A.36})$$

Rearranging of eqn (A.36) results in a more convenient form of the energy equation:

$$\begin{aligned} \frac{\partial \rho H}{\partial t} + \frac{\partial \rho u H}{\partial x} + \frac{\partial \rho v H}{\partial y} = \frac{\partial P}{\partial t} + \frac{\partial}{\partial y} \left[\frac{k}{c_p} \frac{\partial H}{\partial y} \right] \\ + \frac{\partial}{\partial y} \left[(\mu - k/c_p) \frac{\partial (1/2 u u)}{\partial y} \right] \quad (A.37) \end{aligned}$$

Taking the mass-weighted average of equation (A.37) gives,

$$\begin{aligned} \frac{\partial \bar{\rho H}}{\partial t} + \frac{\partial \bar{\rho u H}}{\partial x} + \frac{\partial \bar{\rho v H}}{\partial y} = \frac{\partial \bar{P}}{\partial t} \\ + \frac{\partial}{\partial y} \left[\frac{k}{c_p} \frac{\partial \bar{H}}{\partial y} (1 + \bar{H}'/H) \right] \\ + \frac{\partial}{\partial y} \left[(\mu - k/c_p) \frac{\partial (1/2 \bar{u u} + \bar{u u}' + 1/2 \bar{u}' u')}{\partial y} \right] \quad (A.38) \end{aligned}$$

The mean is then taken of equation (A.38) to obtain

$$\begin{aligned} \frac{\partial \bar{\rho H}}{\partial t} + \frac{\partial \bar{\rho u H}}{\partial x} + \frac{\partial \bar{\rho v H}}{\partial y} = \frac{\partial \bar{P}}{\partial t} \\ + \frac{\partial}{\partial y} \left[\frac{k}{c_p} \frac{\partial \bar{H}}{\partial y} (1 + \bar{H}'/H) \right] \end{aligned}$$

$$+ \frac{\partial}{\partial Y\#} \left[\frac{(\mu\# - k\#/cp\#)}{\partial Y\#} \overline{\left(\frac{1}{2} u\#u\# + u\#u\#' + \frac{1}{2} u\#'u\#' \right)} \right] \quad (A.39)$$

Combining eqn (A.39) with eqns (A.16), (A.17) and (A.18) results in the time and mass-weighted averaged energy equation:

$$\begin{aligned} \frac{\partial \rho\#H\#}{\partial t\#} + \frac{\partial \rho\#u\#H\#}{\partial x\#} + \frac{\partial \rho\#u\#'H\#}{\partial x\#} + \frac{\partial \rho\#v\#H\#}{\partial Y\#} + \frac{\partial \rho\#v\#'H\#}{\partial Y\#} = \frac{\partial P\#}{\partial t\#} \\ + \frac{\partial}{\partial Y\#} \left[\frac{k\#}{cp\#} \frac{\partial H\#(1+H\#'/H\#)}{\partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\frac{(\mu\# - k\#/cp\#)}{\partial Y\#} \overline{\left(\frac{1}{2} u\#u\# \right)} \right] \\ + \frac{\partial}{\partial Y\#} \left[\frac{(\mu\# - k\#/cp\#)}{\partial Y\#} \overline{\left(u\#u\#' + \frac{1}{2} u\#'u\#' \right)} \right] \quad (A.40) \end{aligned}$$

Comparison with Original Equations

The resulting x-momentum equation (A.33) has three terms that make it different than eqn (2.2). These terms are:

$$\frac{\partial \rho\#u\#'u\#}{\partial x\#}, \quad \frac{\partial \rho\#u\#'v\#}{\partial Y\#}, \quad \text{and} \quad \frac{\partial}{\partial Y\#} \left[\mu\# \frac{\partial}{\partial Y\#} \overline{u\#(u\#'/u\#)} \right] \quad (A.41)$$

The energy equation (A.40) has four terms that make it different than equation (A.37). These terms are:

$$\frac{\partial \rho\#u\#'H\#}{\partial x\#}, \quad \frac{\partial \rho\#v\#'H\#}{\partial Y\#}, \quad \frac{\partial}{\partial Y\#} \left[\frac{k\#}{cp\#} \frac{\partial}{\partial Y\#} \overline{H\#(H\#'/H\#)} \right]$$

$$\frac{\partial}{\partial Y\#} \left[(\mu\# - k\#/cp\#) \frac{\partial}{\partial Y\#} \left(\overline{u\#u\#'} + 1/2 \overline{u\#'u\#'} \right) \right] \quad (A.42)$$

An order of magnitude analysis needs to be completed to determine which of these extra seven terms could be neglected.

Appendix B

Substitution of the Closure Equations

After an order of magnitude analysis is completed on the time and mass-weighted averaged energy equation, an extra term exists which is different than the original form of the energy equation. That term is

$$\frac{\overline{\partial \rho \# v \# H \#}}{\partial Y \#} \quad (B.1)$$

However, a closure equation is given in Anderson (3:225) which says

$$\overline{\rho \# c_p \# v \# T \#} = - \mu \# \frac{c_p \#}{T} \frac{\partial T \#}{\partial Y \#} \quad (B.2)$$

From a previous analysis completed in Appendix A, it is known that

$$H' = h' + \overline{u u'} + 1/2 \overline{u' u'} - 1/2 \frac{\overline{\rho u' u'}}{\rho} \quad (A.26)$$

Substituting eqn (A.26) into the term $\overline{\rho \# v \# H \#}$, one obtains

$$\overline{\rho \# v \# H \#} = \overline{\rho \# v \# h \#} + \overline{\rho \# v \# u \# u \#} \quad (B.3)$$

$$\overline{\rho \# v \# H \#} = \overline{\rho \# c_p \# v \# T \#} + \overline{u \# \rho \# u \# v \#} \quad (B.4)$$

Substituting the closure equations for the two terms gives

$$\overline{\rho \# v \# H \#} = - \mu \# \frac{c_p \#}{T} \frac{\partial T \#}{\partial Y \#} - \overline{u \#} \left[\mu \# \frac{\partial u \#}{\partial Y \#} \right] \quad (B.5)$$

Putting eqn (B.5) into a form with the total enthalpy,

$$\overline{\phi_{v\#}'H\#} = - \frac{\mu\#}{Pr} \frac{\partial H\#}{\partial Y\#} + \frac{\mu\#}{Pr} \frac{1}{2} \frac{\partial u\#^2}{\partial Y\#} - u\# \frac{\mu\#}{T} \frac{\partial u\#}{\partial Y\#} \quad (B.6)$$

$$\overline{\phi_{v\#}'H\#} = - \frac{\mu\#}{Pr} \frac{\partial H\#}{\partial Y\#} - \frac{\mu\#}{T} (1 - 1/Pr) \frac{1}{2} \frac{\partial u\#^2}{\partial Y\#} \quad (B.7)$$

The energy equation, as previously developed, has the form:

$$\frac{\partial \phi_{H\#}}{\partial t\#} + \frac{\partial \phi_{u\#H\#}}{\partial x\#} + \frac{\partial \phi_{v\#H\#}}{\partial Y\#} + \frac{\partial \phi_{v\#}'H\#}{\partial Y\#} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[\frac{k\#}{cp\#} \frac{\partial H\#}{\partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\left[\mu\# - \frac{k\#}{cp\#} \right] \frac{\partial (1/2 u\#^2)}{\partial Y\#} \right] \quad (2.15)$$

Rewriting the energy eqn (2.15) using the definition that

$$\frac{k\#}{cp\#} = \frac{\mu\#}{Pr} \quad (B.8)$$

The energy equation (2.15) becomes

$$\frac{\partial \phi_{H\#}}{\partial t\#} + \frac{\partial \phi_{u\#H\#}}{\partial x\#} + \frac{\partial \phi_{v\#H\#}}{\partial Y\#} + \frac{\partial \phi_{v\#}'H\#}{\partial Y\#} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[\frac{\mu\#}{Pr} \frac{\partial H\#}{\partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\mu\# (1 - 1/Pr) \frac{\partial (1/2 u\#^2)}{\partial Y\#} \right] \quad (B.9)$$

Substituting eqn (B.7) into the energy equation (B.9) gives

$$\frac{\partial \phi_{H\#}}{\partial t\#} + \frac{\partial \phi_{u\#H\#}}{\partial x\#} + \frac{\partial \phi_{v\#H\#}}{\partial Y\#} = \frac{\partial P\#}{\partial t\#} + \frac{\partial}{\partial Y\#} \left[\left[\frac{\mu\#}{Pr} + \frac{\mu\#}{T} \right] \frac{\partial H\#}{\partial Y\#} \right] + \frac{\partial}{\partial Y\#} \left[\left[\mu\# (1 - 1/Pr) + \frac{\mu\#}{T} (1 - 1/Pr) \right] \frac{\partial (1/2 u\#^2)}{\partial Y\#} \right] \quad (2.23)$$

Calibration of the VKI H-3 Wind Tunnel

Purpose

To determine the size of the flat plate model to construct, the scope of the Mach 6 uniform free jet must be determined. The first time the tunnel was calibrated was after its installation in 1970 (29). That previous calibration showed the existence of a small centerline disturbance and the slow streamwise growth of the outer shear layer.

This test will examine the streamwise distribution from the nozzle exit, taking measurements every 50 mm. Also the uniformity of the flow at each streamwise position will be examined by rotating the rake 30 degrees at a time from a vertical position until the entire cross-sectional area is examined.

3.3.2 Theory

To determine the uniformity of the flow, a distribution of pitot pressure is measured along various cross sections of the test chamber. The pressure in the reservoir is also monitored throughout the test. The ratio of the reservoir pressure, P_{o1} , and the test chamber total pressure, P_{o2} , gives the Mach number of the flow coming out of the nozzle exit.

The pitot pressure in the test chamber is actually the total pressure behind a normal shock. The normal shock is

present due to the presence of the pitot probe itself. Isentropic flow relations and normal shock theory can be used to find the initial Mach number (35:148). The ratio of total pressures can be written in terms of the initial Mach number.

$$\frac{P_{o1}}{P_{o2}} = \left[\frac{2\gamma}{\gamma+1} M_1^2 - \frac{\gamma-1}{\gamma+1} \right]^{1/(\gamma-1)} \left[\frac{1 + .5(\gamma-1) M_1^2}{.5(\gamma+1) M_1^2} \right]^{\gamma/(\gamma-1)} \quad (E.1)$$

This equation can be rewritten, solving for M_1 , so that

$$M_1^2 = \frac{(\gamma+1)}{2\gamma} \left[\frac{(\gamma-1)}{(\gamma+1)} + \left(\frac{P_{o1}}{P_{o2}} \right)^{\frac{\gamma-1}{\gamma}} [1.5(\gamma+1)] \left[\frac{1}{M_1^2} + .5(\gamma-1) \right] \right]^{-\frac{\gamma}{\gamma-1}} \quad (E.2)$$

An iterative procedure must be used to solve for M_1 since it appears on both sides of the equation. Using an initial guess for M_1 in the equation as 5.999, the solution for the actual M_1 given the total pressure ratios will be obtained very quickly. The Mach number output is compared with the Mach number input, and then the output is used as the next iteration's input. The iteration continues until the difference between the input and output Mach numbers is less than 0.001. A computer program which does this iteration is included in Appendix D.

Description of Equipment

A pitot rake with eleven pitot tubes was used to measure the total pressure in the test chamber. The

detailed dimensions of the pitot rake are given in Figure E.1. The pitot rake tubes originally extended 50 mm ahead of the metal plate support, but due to tunnel blockage problems, the probes were shortened until only 10 mm of the pitot tube extended ahead of the plate support. The shortening of the probes had no effect on the results, but this is discussed in the section on error analysis and repeatability. The probe centerlines are 13 mm apart.

The pitot probes were connected to a Scanl-Valve pressure transducer. The probes were read sequentially during each run, beginning with the number 1 probe and advancing to the number 11 probe. The data was recorded on a Graphispot recorder on advancing graph paper. The total pressure for the reservoir was measured by a pressure transducer and also recorded on a Graphispot recorder. The data acquisition system is shown in Figure E.2.

The installed pressure rake is shown in Figure E.3. This is the position the rake is in during the startup sequence of the tunnel. After the tunnel has started, the rake is injected into the free jet. Figure E.4 shows the position of the rake after injection. In this particular figure, the rake is at an orientation of 120° . Note there is a portion of the diffuser nozzle cut to permit the injection of the rake. Due to tunnel blockage problems, a

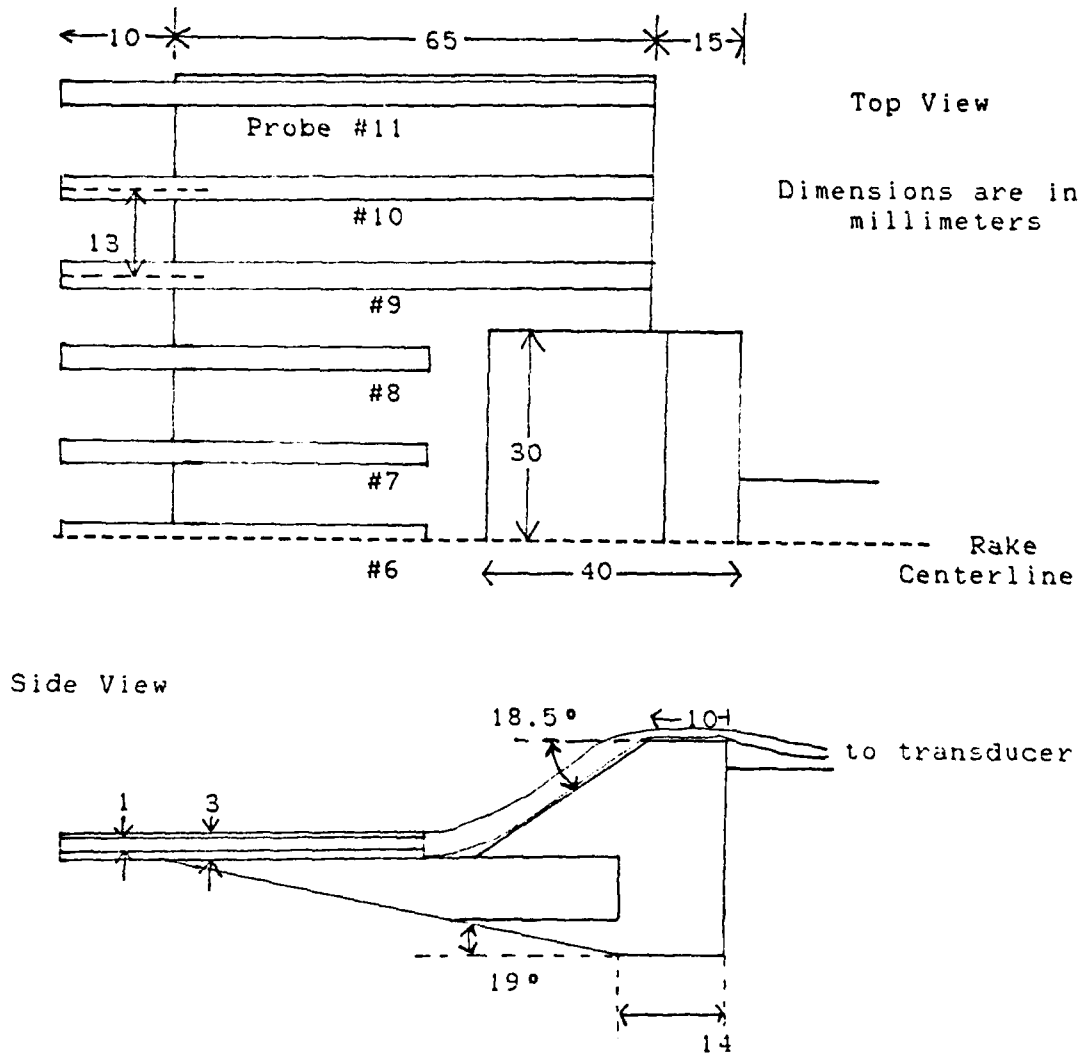

Figure E.1. Pitot Pressure Rake

Figure E.3. Pitot Rake Installed

Figure E.4 Pitot Rake in Injected Position

metal piece was constructed and attached to the rake support to replace the cut portion of the diffuser during the test. After injection, the additional piece fits closely to the diffuser.

The reservoir pressure transducer was calibrated against a manometric balance equipped with precision weights. During tests, the transducer was referenced against atmospheric pressure. The pitot rake transducer was calibrated against a vacuum pump and a mercury manometer. During tests, it also was referenced against atmospheric pressure. The atmospheric pressure was read from a mercury manometer.

The orientation of the injected rake is 0° when the rake is vertical and probe number 1 is on the top. The injected rake is at 90° when it is horizontal and probe number 1 is at the left most position when looking forward toward the reservoir. The other angles, 30° , 60° , 120° , and 150° are defined accordingly.

Results

Data was taken in the streamwise direction up to 143.5 mm from the nozzle exit. The previous studies (1; 14; 15; 53) at VKI had used models that were 296 mm in length and 110 mm in width, so it had originally been intended to calibrate the tunnel as far as 300 mm behind the nozzle exit. However, the tunnel would block after injection of the pressure rake at $x = 150$ mm. After several changes to the wind tunnel and model, the farthest distance the calibration tests were eventually run at was 143.5 mm behind the nozzle exit. At this distance, the data set could be fairly well completed at all the rake orientations.

Tunnel Blockage

The tunnel blockage phenomena is linked to the complexity of the flow which has to pass through the diffuser. The complex flow is composed of the wake of the model, the shock waves formed from the model, and also the distance from the nozzle exit and the diffuser nozzle entrance. It appeared that the tunnel blockage occurrence was primarily a function of the location of the diffuser,

I but still a function of rake orientation and reservoir stagnation pressure.

When the rake was 153.5 mm behind the nozzle exit, blockage occurred at $P_o = 10$ and 20 bars. At this time, the tests at the 90° rake orientation had already been completed. It was at this point that the pressure probes were shortened from 50 mm to 10 mm in length. That way the rake support could be moved closer toward the nozzle exit, and therefore the diffuser nozzle entrance could also be moved closer to the nozzle exit. The tunnel ran for perhaps a second after injection of the rake at 153.5 mm with $P_o = 20$ bars, and then blocked. The rake and diffuser nozzle were moved forward 10 mm and the tunnel ran successfully. However, at 143.5 mm, blockage still occurred when the rake was at 60° and 90° for $P_o = 10$ bars, so no data could be taken at those conditions. However, the tunnel ran for all the orientations at $P_o = 20$ bars at $x=143.5$ mm.

C Although blockage occurred with the rake at 90° , $x = 153.5$ mm and $P_o = 20$ bars, at the end of the calibration tests it was found that the tunnel did not block when the rake was at 150° and $P_o = 20$ bars. It was promising to see that some of the rake orientations were less disturbing to the flow and did not cause tunnel blockage. Unfortunately, time did not permit an extensive study on the tunnel blockage phenomena, so the exact cause of blockage could not be determined.

Error Analysis and Repeatability

The error analysis for the Mach number calculations was completed by examining the equation of total pressure ratio, equation (E.1). The natural logarithm was taken of the entire equation and then each term was partially differentiated with respect to P_{o1} , P_{o2} , or M_1 . The resulting equation is

$$\frac{dP_{o1}}{P_{o1}} - \frac{dP_{o2}}{P_{o2}} = A \frac{dM_1}{M_1} \quad (E.3)$$

where

$$A = \frac{4\gamma M_1^2 / [(\gamma-1)(\gamma+1)]}{[2\gamma M_1^2 / (\gamma+1) - (\gamma-1)/(\gamma+1)]} + \frac{\gamma M_1^2}{[1 + .5(\gamma-1)M_1^2]} + \frac{\gamma(\gamma+1)M_1^2 / (\gamma-1)}{[.5(\gamma+1)M_1^2]} \quad (E.4)$$

If $M_1 = 6.0$ and $\gamma = 1.4$, then $A = 4.17$. The error in Mach number is then

$$\frac{dM_1}{M_1} = \left[\left[\frac{1}{4.17} \frac{dP_{o1}}{P_{o1}} \right]^2 + \left[\frac{1}{4.17} \frac{dP_{o2}}{P_{o2}} \right]^2 \right]^{1/2} \quad (E.5)$$

The same type of analysis is completed on the equations used to calculate P_{o1} and P_{o2} from the graphisplot recorder data, accounting for errors of ± 0.2 mm in the atmospheric pressure readings. P_{o1} varied 1.3 division during a test

while P_{o2} could be read to within 0.3 division and varied 0.3 divisions during a test. This corresponds to errors of

$$dP_{ATM}/P_{ATM} = 0.000263$$

$$dP_{o1}/P_{o1} = 0.0158 \quad \text{for } P_{o1} = 10 \text{ bars}$$

$$dP_{o2}/P_{o2} = 0.0042 \quad \text{for } P_{o1} = 10 \text{ bars}$$

$$dM_1/M_1 = 0.0039 \quad \text{for } P_{o1} = 10 \text{ bars}$$

$$dP_{o1}/P_{o1} = 0.0073 \quad \text{for } P_{o1} = 20 \text{ bars}$$

$$dP_{o2}/P_{o2} = 0.0070 \quad \text{for } P_{o1} = 20 \text{ bars}$$

$$dM_1/M_1 = 0.0024 \quad \text{for } P_{o1} = 20 \text{ bars}$$

(E.6)

The errors in the calibration tests are listed in Table E.1.

Table E.1. Measurement Errors in Calibration

	dM	$d(P_{o2}/P_{o1})$
$P_{o1} = 10 \text{ bars}$	± 0.024	± 0.00035
$P_{o1} = 20 \text{ bars}$	± 0.015	± 0.00022

Several runs were repeated to verify that shortening the probe lengths had no effect on the data taken later. This is shown in Figures E.5 through E.7. Figure E.7 shows results for the probe shortening and also repetition of a test with the same probe length. All the tests are repeatable to within the measurement errors.

Streamwise Flow

The streamwise flow at a radial distance of 39 mm from the centerline is examined by plotting the data from probes 3 and 9 versus streamwise direction, x . The trend of the streamwise flow is shown in Figures E.8 and E.9. For each angle, there are two sets of data, for viewing purposes the number 3 probe was plotted slightly ahead of the probe 9 data, although the probes were actually at the same x location. The trend is a slow rise in Mach number as the distance from the nozzle increases from a mean Mach number of 5.97 to a mean Mach number of 6.00. This is not unexpected as the flow exiting out of the nozzle continues

to expand slightly in the open test section, thereby slightly increasing the flow velocity and Mach number.

The centerline streamwise flow is examined by plotting the data from probe number 6 versus x . It can be seen in Figures E.10 and E.11. The trend of a rise in Mach number is also seen as in the $r = 39$ mm case, but the rise in Mach number is more evident on the centerline. The rise is sudden between $x = 3.5$ mm and 53.5 mm, but then the Mach number increases very slowly, perhaps even becoming constant near Mach = 6.05 after $x = 143.5$ mm.

Cross-sectional Variation

The Mach number is fairly constant over the cross section of the test section with variations of approximately 2 % for the flow at $P_o = 10$ bar and 2.2% for the flow at $P_o = 20$ bar at the center of the flow. This can be seen from Figures E.12 through E.19. The centerline disturbance will be examined in a later section. The flow has been determined to be axisymmetric and after taking into account the measurement error, there are no significant trends due to the angular orientation of the rake.

Comparing the plots at $P_{o1} = 10$ bars, and $P_{o1} = 20$ bars reveals no significant difference between the plots when taking the measurement error into account. This means there are no Reynolds numbers effects for the uniform flow at Mach 6 in the range of Reynolds numbers that have been studied.

Shear Layer

The ratio P_{o2}/P_{o1} is plotted in Figures E.20 through E.23 to illustrate the growth of the shear layer when $P_{o1} = 20$ bars. The boundaries of the shear layer/uniform flow region are shown in Table E.2. The errors in these interpretations are approximately ± 2 mm.

Using the data from Table E.2, the region of uniform flow is sketched in Figure 3.2. The boundary beginning at the nozzle exit is interpolated to 143.5 mm behind the nozzle exit. After $x = 143.5$ mm, the region of uniform flow could be extrapolated to 300 mm behind the nozzle exit. However, the region of uniform flow resulting from the extrapolation appears unrealistic. It is difficult to believe that the shear layer would grow as fast as the extrapolation indicated. Therefore, this seems to indicate that there is not enough information available to draw a conclusion about the extent of the growth of the shear layer farther than the 143 mm after the nozzle exit.

Table E.2. Definition of Uniform Flow Regions

x location (mm)	left edge of shear layer (mm)	right edge of shear layer (mm)	diameter of uniform flow region (mm)
3.5	17 ± 2	134 ± 2	117 ± 2
53.5	16 ± 2	135 ± 2	118 ± 2
103.5	22 ± 2	133 ± 2	111 ± 2
143.5	27 ± 2	125 ± 2	98 ± 2

Centerline Disturbance

A centerline disturbance was evident in every test. This disturbance can be seen in Figures E.12 through E.19. The disturbance was, at worst, approximately 2.2% of the mean flow. The centerline disturbance only affected the center probe at the nozzle exit, but this disturbed region expanded to affect the three center probes (a width of at least 26 mm) at $x = 143.5$ mm from the nozzle exit. The centerline disturbance was negative at the exit and then became a positive disturbance at $x = 53.5$ mm. The centerline flow behaves as if it were a separate jet itself - increasing in Mach number as it expands inside the larger uniform jet of Mach 6.

Conclusions of Calibration

This study shows the presence of a slow growing shear layer and centerline disturbance. These results are similar to those found by an earlier study (29). The extent of the uniform flow has been obtained and the Mach number variations have been shown to be within 2.2% in this uniform flow region.

The flow can be considered to be a uniform axisymmetric jet of Mach 6. The uniform flow has been determined to be approximately 117 ± 2 mm in diameter at the nozzle exit and remains relatively constant until a distance of 103.5 mm downstream of the nozzle exit. The uniform flow then decreases to approximately 98 ± 2 mm in diameter at 143.5 mm

downstream of the nozzle exit. More information needs to be obtained farther downstream of the nozzle exit to determine the extent of the uniform flow. This would entail, not only conducting more tests, but designing a new pressure rake to avoid the occurrence of tunnel blockage.

Appendix F

Preparation of the Liquid Crystal Model (19:25,26; 14:37,38)

The encapsulated liquid crystals are sold as a water-based slurry. After shaking the bottle vigorously, the slurry is then diluted by addition of distilled water (50 to 150% dilution, depending on the batch of liquid crystals). After thorough mixing (several hours) with a small propeller mixer, the slurry is filtered through a thin layer of cotton. If the liquid crystals were not diluted enough, most of the liquid crystals will be trapped in the cotton, and the filtered solution will be mostly composed of water.

The model used for the liquid crystal technique should have a low thermal conductivity so that the heat is not conducted away too rapidly. The surface of the material has to be painted in dull black. This is to prevent light reflections from the underlaying model surface which would overwhelm the intensity changes due to temperature change. This is especially critical if the DIP system is used for the color/temperature correlation. Before applying the coat of liquid crystals, the surface must be degreased with a substance that will not dissolve the paint on the model.

The liquid crystals are then sprayed with an air brush onto the model's surface in very thin layers. Each layer should be at the limit between droplets and a completely wet film. The first layer should be allowed to dry thoroughly

I
in the surrounding air. It is the basis for all subsequent layers and has to provide the bonding to the model. The other layers can be dried quickly with a hair dryer. The hair dryer will also act as a heater, so the quality of the liquid crystal layer can be easily inspected. The most critical color is the red, and if it shows up properly, the model is ready.

A damaged coat of liquid crystals can be removed under running water by wiping with a soft cloth. The remaining particles of liquid crystals can be easily removed with a methanol soaked cloth. The gelatin of the microcapsules is destroyed by methanol.

Appendix G

Digital Image Processing

The use of the digital image processing (DIP) makes the liquid crystal technique more quantitative by taking the subjectiveness out of determining the temperature from a color picture. The system works directly from a video frame. It works with a black and white version of the frame and according to the gray intensity of a point (pixel), a "false color" is assigned to it. The VKI system distinguishes between 256 shades of gray from black (intensity 0) to white (intensity 255).

The critical link between the DIP and the liquid crystal technique is the calibration of the liquid crystals. The calibration gives the correlation between the "false color" (intensity) and the temperature.

The use of a video camera complicates this system somewhat. In order to photograph the model, a bright light must be used to illuminate the model. However, the variations in the intensity of this bright light overwhelms the intensity variations due to temperature changes. A solution to this problem is to film the model (with no temperature changes) when illuminated by the bright light. This picture represents the intensity variations due only to the lighting. The intensities of this "reference" frame are then subtracted appropriately from the calibration and test video frames.

I

The correlation between temperature and intensity, after correcting for the reference frame intensity, can now be used, but with a precaution. The relation of intensity to temperature is multi-valued, i.e., there are two different colors for one intensity. Hence, the analysis requires a simultaneous inspection of the video image and the intensity curve of the corrected picture. Once the surface temperatures are obtained, the heat transfer rate and Stanton number can be determined.

Several computer programs are used in the processing of the liquid crystal video frames and are located in the VKI PDP computer under the account name CREUSOT. Some explanations concerning the computer programs are located in several references (14:12-14; 12:35-39).

Appendix H

Electrical Analog Circuits

The surface heat flux is deduced from temperature versus time signals using electrical analog circuits. Each of these circuits consists of a series of resistances and capacitances in which voltages and currents behave in ways similar to temperatures and heat fluxes, respectively.

The following is a comparison of the thermal and electrical equations, and is extracted from Schultz and Jones (48:37,38). Further behavior of the analog circuit is described and is extracted from Ligrani, Camci, and Grady (37:16-20).

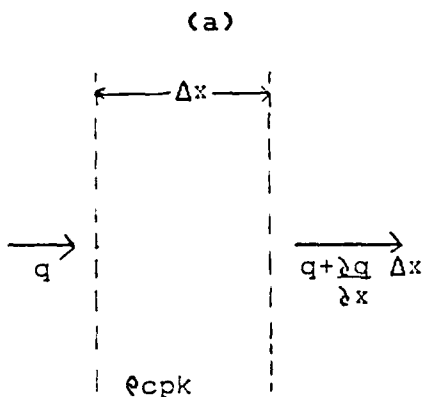

Figure H.1a.
Thermal Circuit

Rate of gain of energy in
element Δx

$$= - \frac{\lambda q}{\Delta x} \Delta x$$

which by conservation of
energy

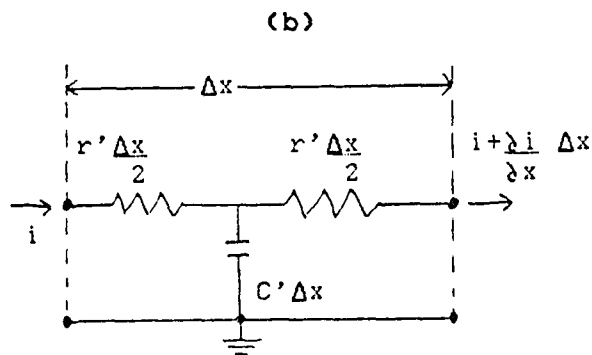

Figure H.1b.
Electrical Circuit

Rate of gain of charge in
element Δx

$$= - \frac{\lambda i}{\Delta x} \Delta x \quad (H.1)$$

which by conservation of
charge

$$= \rho_{cp} \Delta x \frac{\partial T}{\partial t} = C' \Delta x \frac{\partial V}{\partial t} \quad (H.2)$$

Thus

$$\frac{\partial q}{\partial x} = - \rho_{cp} \frac{\partial T}{\partial t}$$

Thus

$$\frac{\partial i}{\partial x} = - C' \frac{\partial V}{\partial t} \quad (H.3)$$

The conduction equation is:

$$q = - k \frac{\partial T}{\partial x}$$

Ohm's law is:

$$i = - \frac{1}{r' \Delta x} \frac{\Delta V}{\Delta x} \Delta x = - \frac{1}{r'} \frac{\partial V}{\partial x} \quad (H.4)$$

Combining the above equations and the diffusion equation is obtained

$$\frac{\partial^2 T}{\partial x^2} = \frac{\rho_{cp}}{k} \frac{\partial T}{\partial t}$$

Combining the above equations and the transmission line equation is obtained

$$\frac{\partial^2 V}{\partial x^2} = r' C' \frac{\partial V}{\partial t} \quad (H.5)$$

It is evident from equations (H.5a) and (H.5b), that the heat diffusion equation is analogous to the electrical transmission line equation. Taking the Laplace transform of equation (H.5b),

$$\frac{\partial^2 V^*}{\partial x^2} = r' C' [s V^* + V(t=\infty) - V(t=0)] \quad (H.6)$$

where $V(t=\infty) = 0$.

The initial condition is

$$V^* = 0 \quad \text{at } t = 0 \quad (H.7)$$

and the boundary conditions are

$$V^* = 0 \quad \text{at } x = \infty \quad (H.8)$$

$$- \frac{1}{r'} \frac{\partial V^*}{\partial x} = i^*_{\text{input}} \quad \text{at } x = 0 \quad (H.9)$$

Applying the initial condition to equation (H.6) and solving the differential equation obtained in V^* and x gives:

$$V^* = A \exp [x (r' C' s)^{1/2}] + B \exp [-x (r' C' s)^{1/2}] \quad (H.10)$$

where A and B are constants. The boundary condition (H.8) gives A=0, and after using the boundary condition (H.9),

$$\frac{\partial V^*}{\partial x} = -(r' C' s)^{1/2} B \exp [-x (r' C' s)^{1/2}] = - i^*_{\text{input}} r' \quad (H.11)$$

or alternatively,

$$B = i^*_{\text{input}} [r' / (C' s)]^{1/2} \quad (H.12)$$

So when $x = 0$, using equations (H.10) and (H.12), the voltage ΔV at the input of the analog circuit, shown in Figure H.2, is given by

$$\Delta V^* = i^*_{\text{input}} [r' / (C' s)]^{1/2} \quad (H.13)$$

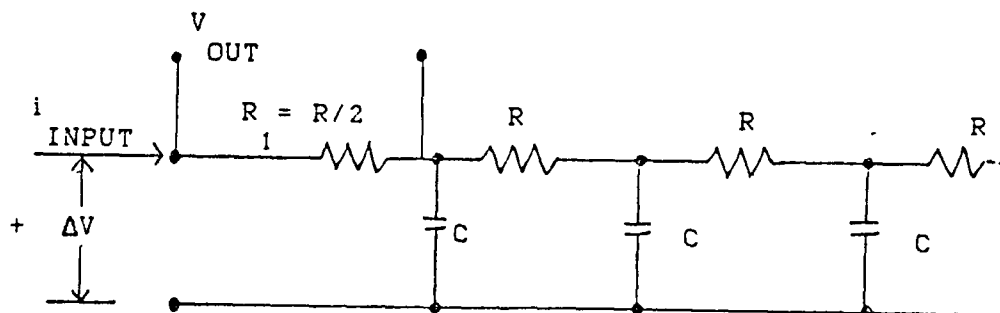

Figure H.2 Electrical Analog Using Equal Sections Representing a Homogeneous Heat Conductor

Using equation (3.26) which is repeated here

$$\frac{\Delta V}{\alpha \frac{V_{REF}}{R}} = T_s \quad (H.14)$$

the circuit input is now the thin film output,

$$\Delta V_s = \alpha \frac{V_{REF}}{R} T_{s*} \quad (H.15)$$

Substituting equation (H.15) into (H.13) and rearranging,

$$i_{*input} = (sC'/r')^{1/2} \alpha \frac{V_{REF}}{R} T_{s*} \quad (H.16)$$

Now the heat conduction equation (15:57-60) analogous to equation (H.13) is

$$q_s = (\rho c p k s)^{1/2} T_{s*} \quad (H.17)$$

So substituting into equation (H.17) for T_{s*} using equation (H.16) gives

$$q_s = (\rho c p k)^{1/2} (r'/C')^{1/2} (\alpha \frac{V_{REF}}{R})^{-1} i_{*input} \quad (H.18)$$

For the analog termination shown in Figure H.2, equation (H.18) after inversion then becomes

$$q_s = (\rho c p k)^{1/2} (r'/C')^{1/2} (\alpha \frac{V_{REF}}{R})^{-1} \frac{V_{OUT}}{R} \quad (H.19)$$

For the substrate heat transfer behavior, the values of q_s obtained from equation (3.32), which is repeated here

$$q_s = \frac{1}{2} (\rho c p k \pi / t)^{1/2} \frac{\Delta V}{\alpha \frac{V_{REF}}{R}} \quad (H.20)$$

and equation (H.18) must be the same provided that q_s is a constant for $t > 0$ and that $T_a = T_{REF}$. Thus,

$$q_s = (\rho c p k \pi / t)^{1/2} \frac{\Delta V}{2 \alpha V_{REF} R} = (\rho c p k)^{1/2} (r' / C')^{1/2} \frac{V_{OUT}}{\alpha V_{REF} R} \quad (H.21)$$

If a calibration of circuits is then made with a step in heat flux, a calibration coefficient for the analog time may then be defined using

$$\frac{A^*}{\beta} = (r' / C')^{1/2} (1/R)^{1/2} = \frac{\Delta V}{2 V_{OUT}} (\pi / t)^{1/2} \quad (H.22)$$

This single time dependent calibration coefficient thus defines the characteristics of the analog circuit in relation to heat flow. Heat fluxes for gages operating when $T_a = T_{REF}$ are obtained by substituting ΔV from equation (H.22) into equation (H.21) to give the equation

$$q_s = \frac{V_{OUT}}{V_{REF}} \frac{(\rho c p k)^{1/2}}{\alpha} \frac{A^*}{\beta} \quad (H.23)$$

which is then used for heat transfer data reduction with the temperature correction on α , if required.

Circuit Considerations

The actual values of r' and C' in equation (H.18) required in an analog circuit are dependent on many factors. Any arrangement of resistive and capacitive components represents semi-infinite heat transfer behavior provided that the value of $r'C'$ (which is analogous to $\rho c p k$) is

constant with time. Two performance criteria by which circuits are judged are

- a) response time - the time required for the analog output to fully account for an alteration in heat transfer rate, ie., voltage input signal, and
- b) operation time - the time after the first input to the analog that the output signal represents a particular heat transfer profile to a stated accuracy.

The aim in analog circuit design is to minimize response time and maximize operation time.

The T-section analog circuit, shown in Figure H.2, has a short response time. For a circuit with all stages of identical component values, this response time is RC . The operation time for which this circuit reproduces a step input in heat transfer to within 1.4% is given by

$$0.2n^2(RC) \quad (H.24)$$

where n is the number of stages. When long operating times are required, arithmetically increasing component values are used, as shown in Figure H.3. For the purpose of calculating operating times from equation (H.24), n T-section analog stages of arithmetically increasing values of capacitance and resistance are equivalent to

$$h(h+1)/2 \quad (H.25)$$

identical stages. When using arithmetically increasing components, the first two stages must be identical if the

frequency response of the circuit is to be acceptable. Figure H.3 shows the analog circuit used in this study, with 24 stages, $R = 4099$ ohms, $C = 20 \times 10^{-9}$ farads, an operating time of 1.4 seconds and a response time of 8.2×10^{-5} seconds.

Appendix I

Calibration of Thin Film Gages

The equation used for heat flux measurements is equation (3.36), but the equation will be repeated here for completeness.

$$q_s = \frac{VOUT}{VREF} \frac{(\rho_{cpk})^{1/2}}{\alpha_R} \frac{A^*}{\beta} [1 + \alpha (T_a - T_{REF})] \quad (I.1)$$

The determination of different parts of equation (I.1); $VREF$, α_R , $(\rho_{cpk})^{1/2}$, and A^*/β , will be discussed in detail. The $[1 + \alpha (T_a - T_{REF})]$ correction term has been previously discussed. These details are extracted from Ligrani, Camci, and Grady (37:24-33).

Output Voltage: VOUT

The output voltage from the analog circuit, VOUT, is different from the other terms in equation (I.1) because it is dependent on the heat flux to a particular gage during specific flow conditions. The other terms in equation (I.1) are determined from sensor or measurement chain calibration characteristics.

Temperature Coefficient of Resistance : α_R

The temperature coefficient of resistance, α_R , of a thin film gage depends on a variety of factors including the film material, the size of the film metal deposit, and its shape. Therefore each gage film must be calibrated

independently since it is impossible to make each film exactly the same.

The temperature coefficient of resistance is defined by

$$R = R_{REF} [1 + \alpha_R (T - T_{REF})] \quad (I.2)$$

This can be rewritten

$$\frac{R - R_{REF}}{T - T_{REF}} = \alpha_R \quad (I.3)$$

where T_{REF} is some reference temperature. The magnitude of $(R - R_{REF}) / (T - T_{REF})$ is found by plotting resistance versus temperature for a given gage and then calculating the slope. This can also be done mathematically by using a least squares algorithm to find the slope of the line between all the data points. The program used for this calculation is listed in Appendix J. R_{REF} is determined by measuring the resistance of the gage and its connecting wires just before input to an analog circuit bridge.

The calibration may be performed in an oil bath. A multimeter is used to measure the film resistances at a range of constant oil bath temperatures. The range of temperatures to calibrate against is determined by the range of temperatures that the gages will be used. The value of α_R may be obtained from the experimental readings using a least squares program.

Experience has shown that maintaining constant oil bath temperature during readings is very critical. This is easiest to accomplish when the oil bath is being cooled

between readings. If constant bath temperatures are maintained during readings, then the accuracy of the calibration is governed by the accuracies of the multimeter and thermometer.

1/2

Substrate Thermal Product: (θ_{cpk})

1/2

The substrate thermal product is (θ_{cpk}). For quartz substrates, the value of the thermal product is well known between ambient and 100°C. However, the thermal product for machinable ceramic substrates are not well defined. The value of the thermal product depends on the history of the gage construction, in particular the high temperature baking details of the ceramic production process. Therefore, when the gages are completed, each ceramic piece must be calibrated.

The thermal product of ceramic will vary with test temperature, so calibration must be completed under the same conditions for which the gages will be used. An arrangement for calibration would consist of a quartz gage and a sample ceramic gage on a flat test plate in the VKI CT-2 tunnel at the same distance downstream of the leading edge. The sample ceramic gage must have been made at the same time as the actual test gage so as to have undergone the same production process. The heat flow is then calculated from the quartz gage readings. The value of q_s obtained is substituted into equation (I.1) to give

$$(\rho_{cpk})_{\text{ceramic}}^{1/2} = q \frac{V_{REF}}{V_{OUT}} \alpha \frac{1}{R A^*/\beta} \frac{1}{[1 + \alpha (T_a - T_{REF})] R} \quad (I.4)$$

Calibration Constant for the Electrical Analog: A^*/β

Once the electrical analog circuits are set up to process the signals from thin film gages they are ready to be calibrated. The purpose of the analog circuit calibration is to obtain A^*/β in equation (I.1). Recall that the calibration constant is defined from Appendix H as

$$\frac{A^*}{\beta} = \frac{\Delta V}{2V_{OUT}} (\pi/t)^{1/2} \quad (I.5)$$

If a parabolic voltage signal is inserted into the input of the analog circuit, then the output is a step in voltage, V_{OUT} . In actual practice, V_{OUT} is measured in digital data units in order to calibrate both the analog circuit as well as the other parts of the measurement chain before the computer: amplifier, filter, multiplexer, analog/digital converter. Therefore, equation (I.5) becomes

$$\frac{A^*}{\beta} = \frac{\Delta V}{2N_{OUT}} (\pi/t)^{1/2} \quad (I.6)$$

and during an actual measurement, equation (I.1) is changed to

$$q_s = \frac{N_{OUT} (\rho_{cpk})}{V_{REF}} \frac{A^*}{\beta} \frac{1}{R} [1 + \alpha (T_a - T_{REF})] \quad (I.7)$$

where N_{OUT} is V_{OUT} measured in digital data units.

Vita

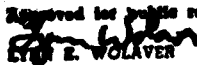

Alice J. Chen was born on 20 November 1958 in Chattanooga, Tennessee. She graduated from Carlsbad High School, Carlsbad, California in 1976 and entered the University of California; San Diego. She graduated in 1980 with a Bachelor of Arts degree in Chemistry. After graduation she received a commission in the USAF after completing training at the Air Force Officer Training School. Her first assignment was to the Air Force Institute of Technology (AFIT), Wright-Patterson Air Force Base, Ohio. She was enrolled in the Undergraduate Engineering Conversion Program and graduated in 1982 with a Bachelor of Science degree in Aeronautical Engineering. Upon graduation, she was assigned to the Air Force Armament Laboratory, Eglin AFB, Florida. She worked as an aeronautical engineer in the Weapon Separations Team, Aerodynamics Branch until May 1984 when she entered the School of Engineering at AFIT. As part of her AFIT assignment, she conducted experimental research during a six month visit at the von Karman Institute for Fluid Dynamics (VKI) in Rhode-Saint-Genese, Belgium, under the AFIT/VKI Exchange Program which was sponsored by HQ USAF, AFIT, VKI, and the Air Force Flight Dynamics Laboratory.

This study combines the techniques of computational fluid dynamics and experimentation.

An unsteady laminar boundary layer code was shown to be more efficient when modified to solve the momentum and energy equations using Thomas' algorithm instead of optimized successive overrelaxation (SOR). A steady eddy viscosity turbulence model was then added to the code: two models for the inner region, Van Driest and Chapman, and two models for the outer region, a mixing length and Clauser were used. The computer code was verified against theoretical and experimental data from the literature. The code shows excellent results for laminar flow and each of the models showed very good agreement with turbulent experimental data.

The experimental study was conducted in a Mach 6 blowdown wind tunnel. Oil flow, sublimation, liquid crystals, and thin film gages were used to examine the flow structure and heat transfer on a flat plate. The heat transfer rates from these gages were lower than from the liquid crystals. The viscid-inviscid interaction flow region of flow past a blunt fin mounted on the flat plate was examined using the same flow visualization methods and possible flow interaction models are presented. Striation heating appeared when the fin incidence was 40° and the sweep was 60 or 75° .

The numerical and experimental techniques of this study were then merged. The heat transfer results from the flat plate experiment were compared with results from the computer code and were found to be in good agreement. (The)
